FOREWORD

The National Toxicology Program (NTP) is made up of four charter agencies of the U.S. Department of Health and Human Services (DHHS): the National Cancer Institute (NCI), National Institutes of Health; the National Institute of Environmental Health Sciences (NIEHS), National Institutes of Health; the National Center for Toxicological Research (NCTR), Food and Drug Administration; and the National Institute for Occupational Safety and Health (NIOSH), Centers for Disease Control. In July 1981, the Carcinogenesis Bioassay Testing Program, NCI, was transferred to the NIEHS. The NTP coordinates the relevant programs, staff, and resources from these Public Health Service agencies relating to basic and applied research and to biological assay development and validation.

The NTP develops, evaluates, and disseminates scientific information about potentially toxic and hazardous chemicals. This knowledge is used for protecting the health of the American people and for the primary prevention of disease.

The studies described in this Technical Report were performed under the direction of the NIEHS and were conducted in compliance with NTP laboratory health and safety requirements and must meet or exceed all applicable federal, state, and local health and safety regulations. Animal care and use were in accordance with the Public Health Service Policy on Humane Care and Use of Animals. The prechronic and chronic studies were conducted in compliance with Food and Drug Administration (FDA) Good Laboratory Practice Regulations, and all aspects of the chronic studies were subjected to retrospective quality assurance audits before being presented for public review.

These studies are designed and conducted to characterize and evaluate the toxicologic potential, including carcinogenic activity, of selected chemicals in laboratory animals (usually two species, rats and mice). Chemicals selected for NTP toxicology and carcinogenesis studies are chosen primarily on the bases of human exposure, level of production, and chemical structure. Selection *per se* is not an indicator of a chemical's carcinogenic potential.

These NTP Technical Reports are available for sale from the National Technical Information Service, U.S. Department of Commerce, 5285 Port Royal Road, Springfield, VA 22161 (703-487-4650). Single copies of this Technical Report are available without charge while supplies last from Central Data Management, NIEHS, P.O. Box 12233, MD A0-01, Research Triangle Park, NC 27709 (919-541-1371).

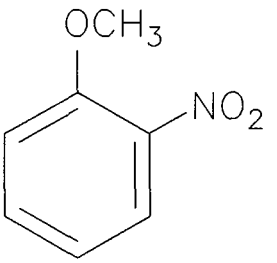
CONTENTS

ABSTRACT



o-NITROANISOLE

CAS No. 91-23-6

Chemical Formula: $C_7H_7NO_3$ Molecular Weight: 153.13

Synonyms: Methoxynitrobenzene, nitrophenyl methyl ether

o-Nitroanisole is used as an intermediate for the preparation of *o*-anisidine and in the manufacture of azo dyes. Toxicology and carcinogenesis studies were conducted by administering *o*-nitroanisole (>99% pure) in the diet to groups of male and female F344 rats and B6C3F$_1$ mice for 14 days, 13 weeks, and 2 years. Genetic toxicology studies were conducted in *Salmonella typhimurium*, Chinese hamster ovary cells, and mouse lymphoma cells.

14-Day Studies

Groups of five male and five female F344 rats received diets containing 0, 583, 1,166, 2,332, 4,665, or 9,330 ppm *o*-nitroanisole. Mean body weight gains and final mean body weights of males in the 4,665 and 9,330 ppm groups were lower than those of the controls. Absolute liver weights were significantly increased in males receiving 1,166 ppm or more and in females receiving 583 ppm or more.

Groups of five male and five female B6C3F$_1$ mice received diets containing 0, 250, 500, 1,000, 2,000, or 4,000 ppm *o*-nitroanisole. Mean body weight gains and final mean body weights of males that received 250 ppm and females that received 4,000 ppm were significantly lower than those of the controls. No other chemical-associated effects were observed.

13-Week Studies

Groups of 10 male and 10 female F344 rats received diets containing 0, 200, 600, 2,000, 6,000, or 18,000 ppm *o*-nitroanisole. Final mean body weights and feed consumption by male and female rats receiving 6,000 and 18,000 ppm were lower than those of the controls. Hemoglobin and hematocrit values were significantly lower and methemoglobin levels significantly higher in males in the 6,000 and 18,000 ppm groups than in controls. Absolute liver weights were significantly increased in females that received 200, 600, 2,000, and 6,000 ppm, absolute kidney weights were significantly increased in males that received 600, 2,000, and 6,000 ppm, and absolute spleen weights were significantly increased in males and females that received 6,000 and 18,000 ppm.

Groups of 10 male and 10 female B6C3F$_1$ mice received diets containing 0, 60, 200, 600, 2,000, or 6,000 ppm *o*-nitroanisole. Final mean body weight gains, final mean body weights, and feed consumption by male and female mice receiving 6,000 ppm were lower than those of the controls. Hemoglobin and hematocrit values in males and females that received 2,000 or 6,000 ppm were significantly lower than those in the controls. The absolute and relative liver weights of females in the 600 ppm group and relative liver weights of males and females in the 2,000 and

6,000 ppm groups were significantly greater than those of controls.

Lesions associated with exposure to *o*-nitroanisole were present in the urinary bladder, spleen, kidney, liver, testis, and uterus of rats. Diffuse hyperplasia of the transitional epithelium of the urinary bladder occurred in all male and female rats that received 6,000 and 18,000 ppm. A transitional cell papilloma occurred in one male and transitional cell carcinomas occurred in two males and three females receiving 18,000 ppm. Congestion of the red pulp and capsular hyperplasia of the spleen and hepatocellular hypertrophy of the liver were present in males and females from the 18,000 ppm groups. Multifocal degeneration and necrosis of the renal tubule epithelium with infiltration of mononuclear inflammatory cells were present in male rats that received 600, 2,000, and 6,000 ppm. At the 18,000 ppm level, degeneration of the seminiferous epithelium accompanied by loss of spermatogenic cells and decreased numbers of spermatozoa were observed in the testes of male rats, while uterine atrophy was observed in female rats.

Hepatocyte hypertrophy of the centrilobular and midzonal regions of liver lobules was present in mice that received 200 ppm and increased in severity at higher exposure levels.

2-YEAR STUDIES

The doses selected for the 2-year study of *o*-nitroanisole in rats were based on lower mean body weights, reduced feed consumption, and increased severity of regenerative anemia in male and female rats receiving 6,000 and 18,000 ppm during the 13-week study. Groups of 60 male and 60 female F344 rats received diets containing 0, 222, 666, or 2,000 ppm *o*-nitroanisole. Groups of 60 male and 60 female B6C3F$_1$ mice received diets containing 0, 666, 2,000, or 6,000 ppm *o*-nitroanisole. After 15 months, up to 10 animals from each group were evaluated for chemical-related lesions.

Survival, Body Weights, Feed Consumption, and Clinical Findings

Survival of male rats receiving 2,000 ppm was significantly lower than that of the controls due to increased severity of nephropathy. Survival of 222 and 666 ppm male rats and all exposed female rats was similar to that of the controls. Survival of groups of exposed male and female mice was similar to that of the controls. The final mean body weight of male rats receiving 2,000 ppm was lower than that of the controls. Final mean body weights of male and female mice that received 2,000 and 6,000 ppm were lower than those of the controls. Feed consumption by male and female rats was similar to that by the controls. The only clinical finding in male or female mice attributable to chemical administration was discolored urine.

Neoplasms and Nonneoplastic Lesions

The incidence of mononuclear cell leukemia was significantly increased in male rats that received 666 and 2,000 ppm and in female rats that received 2,000 ppm (males: 0 ppm, 26/50; 222 ppm, 25/50; 666 ppm, 42/50; 2,000 ppm, 34/50; females: 14/50, 11/50, 14/50, 26/50). Nephropathy occurred in all male rats; the severity increased with exposure level. Focal hyperplasia of the renal tubule epithelium was present in three males receiving 222 ppm and two males receiving 2,000 ppm. Renal tubule adenomas occurred in one male from each of the 222, 666, and 2,000 ppm groups, and renal tubule carcinomas occurred in two males from the 2,000 ppm group. Focal hyperplasia of the transitional epithelium of the urinary bladder was present in one female rat that received 222 ppm and two male rats and six female rats that received 2,000 ppm. A transitional cell papilloma occurred in the urinary bladder of one female rat from the 2,000 ppm group, and a transitional cell carcinoma occurred in another female from the 2,000 ppm group. The incidence of forestomach ulcers increased in male rats that received 2,000 ppm, and the incidence of focal hyperplasia of the forestomach increased with exposure level in male and female rats. In addition, squamous cell papillomas of the forestomach were present in one female receiving 222 ppm, one male receiving 666 ppm, and one male and one female receiving 2,000 ppm, while squamous cell carcinomas were present in one male receiving 666 ppm and one male and one female receiving 2,000 ppm. The incidences of pituitary gland adenomas in male rats and mammary gland fibroadenomas in female rats decreased with exposure level.

The incidence of cellular alteration in the liver was significantly increased in exposed groups of male and female mice. The incidences of hepatocellular adenoma, hepatocellular adenoma or carcinoma (combined), and hepatocellular carcinoma or hepatoblastoma (combined) were significantly

increased in male mice receiving 2,000 and 6,000 ppm. The incidences of hepatocellular adenoma or carcinoma were significantly increased in female mice that received 2,000 ppm.

Stop-Exposure Study

Groups of 60 male and 60 female F344 rats received diets containing 0, 6,000, or 18,000 ppm *o*-nitroanisole for 27 weeks and were then maintained on control feed without further chemical exposure for up to an additional 77 weeks. Up to 10 rats from each group were evaluated for the presence of chemical-related lesions at 3, 6, 9, and 15 months.

Survival and Body Weights

Survival of exposed male and female rats was significantly lower than that of the controls as a result of moribund deaths associated with significantly increased incidences of urinary bladder neoplasms, primarily transitional cell carcinomas. All male rats that received 18,000 ppm were dead by week 48 and all females that received 18,000 ppm were dead by week 61. Mean body weights of exposed male and female rats were lower than those of the controls throughout the study.

Neoplasms and Nonneoplastic Lesions

Hyperplasia of the transitional epithelium of the urinary bladder was present in nearly all exposed male and female rats examined at the interim evaluations. A transitional cell carcinoma was first observed at the 3-month interim evaluation in a male rat that received 18,000 ppm. At the 6- and 9-month interim evaluations, transitional cell papillomas or carcinomas were observed in both exposed groups of male rats. Transitional cell carcinomas were observed at the 6-month interim evaluation in females receiving 18,000 ppm and at the 9-month interim evaluation in females receiving 6,000 and 18,000 ppm.

Adenomatous polyps of the large intestine were observed in a small number of exposed rats at the 6-, 9-, and 15-month interim evaluations. At the end of the study, the incidence of adenomatous polyps of the large intestine was significantly increased in all exposed groups and carcinomas of the large intestine were present in four males and two females from the 18,000 ppm groups. The incidence of hyperplasia of the transitional epithelium of the kidney pelvis was significantly increased in exposed male and female rats and transitional cell papillomas were present in three males and one female that received 18,000 ppm. Transitional cell carcinomas of the kidney were present in one male receiving 6,000 ppm and six males and one female receiving 18,000 ppm. Transitional cell carcinomas of the urinary bladder were seen in nearly all exposed male and female rats. Of the males and females receiving 6,000 ppm which were without carcinomas, three males and one female had transitional cell papillomas.

Generalized centrilobular hypertrophy, focal hepatocellular necrosis, multifocal hepatocellular cytoplasmic vacuolation, and Kupffer cell pigmentation were observed in the livers of male and female rats at the 3- and 6-month interim evaluations; however, only Kupffer cell pigmentation was observed at the end of the study. Congestion of the red pulp of the spleen was observed in nearly all exposed male and female rats at the 3-, 6-, and 9-month interim evaluations but the incidence was only slightly increased in the 18,000 ppm groups at the end of the study. Degeneration and atrophy of the seminiferous tubule epithelium of the testes were observed at the 3- and 6-month interim evaluations in all male rats receiving 18,000 ppm.

Genetic Toxicology

o-Nitroanisole was tested in two laboratories for mutagenicity in *Salmonella typhimurium* strains TA97, TA98, TA100, TA1535, and TA1537 with and without exogenous metabolic activation (S9). Positive responses were observed at both laboratories in TA100 with and without S9 activation. One laboratory found no increase in mutations, while the second laboratory detected a weakly positive response in TA1535 without S9. No mutagenic activity was observed in the other tester strains. *o*-Nitroanisole was positive in the mouse lymphoma assay for induction of trifluorothymidine resistance in L5178Y cells without S9 activation. In cytogenetic tests with Chinese hamster ovary cells, *o*-nitroanisole induced a significant increase in chromosomal aberrations at the highest dose tested in the presence of S9 activation; sister chromatid exchanges were induced both with and without S9.

CONCLUSIONS

Under the conditions of these feed studies there was *clear evidence of carcinogenic activity** of *o*-nitroanisole in male and female F344 rats that received diets containing 6,000 or 18,000 ppm for 6 months based on overall increased incidences of benign and malignant neoplasms of the urinary bladder, transitional cell neoplasms of the kidney, and benign and malignant neoplasms of the large intestine. There was a chemical-related increased incidence of mononuclear cell leukemia in male and female rats receiving diets containing 222, 666, or 2,000 ppm *o*-nitroanisole for 2 years. Marginally increased incidences of uncommon renal tubule neoplasms in male rats and forestomach neoplasms in male and female rats were considered uncertain findings. There was *clear evidence of carcinogenic activity* of *o*-nitroanisole in male $B6C3F_1$ mice based on increased incidences of benign and malignant hepatocellular neoplasms. There was *some evidence of carcinogenic activity* of *o*-nitroanisole in female $B6C3F_1$ mice based on increased incidences of hepatocellular adenomas.

Increased severity of nephropathy in male rats, and increased incidences of focal hyperplasia of the renal tubule epithelium and forestomach ulcers in male rats, and of transitional cell hyperplasia of the urinary bladder, focal hyperplasia of the forestomach, and hyperplasia of transitional epithelium of the kidney pelvis in male and female rats were associated with exposure to *o*-nitroanisole.

---

* Explanation of Levels of Evidence of Carcinogenic Activity is on page 12. A summary of the Technical Reports Review Subcommittee comments and the public discussion on this Technical Report appear on page 14.

Summary of the 2-Year Carcinogenesis and Genetic Toxicology Studies of *o*-Nitroanisole

	Male F344 Rats		Female F344 Rats	
	2-Year Study	Stop-Exposure Study[a]	2-Year Study	Stop-Exposure Study[a]
Doses	0, 222, 666, or 2,000 ppm in feed	0, 6,000, or 18,000 ppm in feed	0, 222, 666, or 2,000 ppm in feed	0, 6,000, or 18,000 ppm in feed
Body weights	High-dose group lower than controls	Exposed groups lower than controls	Exposed groups similar to controls	Exposed groups lower than controls
2-Year survival rates	32/50, 34/50, 24/50, 9/50	13/20, 1/20, 0/20	33/50, 41/50, 26/50, 33/50	14/20, 4/20, 0/20
Nonneoplastic effects	Forestomach: focal hyperplasia (3/50, 16/50, 25/50, 32/50); ulcers (3/50, 3/50, 8/50, 16/50) Kidney: renal tubule focal hyperplasia (0/49, 3/50, 0/50, 2/49); nephropathy severity (2.2, 2.4, 2.6, 3.2)	Urinary bladder: transitional cell hyperplasia (0/59, 38/59, 11/60) Kidney: transitional epithelium hyperplasia (5/60, 34/60, 27/60)	Forestomach: focal hyperplasia (8/50, 8/50, 13/50, 28/50)	Urinary bladder: transitional cell hyperplasia (0/58, 34/59, 11/60) Kidney: transitional epithelium hyperplasia (0/60, 6/60, 19/60)
Neoplastic effects	All organs: mononuclear cell leukemia (26/50, 25/50, 42/50, 34/50)	Urinary bladder: transitional epithelium papilloma (0/59, 9/59, 1/60); transitional epithelium carcinoma (0/59, 27/59, 50/60); squamous cell papilloma (0/59, 0/59, 4/60); squamous cell carcinoma (0/59, 0/59, 6/60); sarcoma (0/59, 2/59, 9/60) Large intestine: adenomatous polyp (0/60, 26/60, 30/60); carcinoma (0/60, 0/60, 5/60) Kidney: transitional epithelium papilloma (0/60, 0/60, 4/60); transitional epithelium carcinoma (0/60, 1/60, 8/60)	All organs: mononuclear cell leukemia (14/50, 11/50, 14/50, 26/50)	Urinary bladder: transitional epithelium papilloma (0/58, 2/59, 1/60); transitional epithelium carcinoma (0/58, 28/59, 48/60); sarcoma (0/58, 2/59, 14/60); squamous cell papilloma (0/58, 0/59, 4/60); squamous cell carcinoma (0/58, 0/59, 1/60) Large intestine: adenomatous polyp (0/60, 8/60, 18/60); carcinoma (0/60, 0/60, 2/60) Kidney: transitional epithelium papilloma (0/60, 0/60, 1/60); transitional epithelium carcinoma (0/60, 0/60, 1/60)

Summary of the 2-Year Carcinogenesis and Genetic Toxicology Studies of *o*-Nitroanisole (continued)

Genetic toxicology	
Salmonella typhimurium gene mutation	Positive with or without S9 in strain TA100; positive without S9 in strain TA1535; negative with or without S9 in strains TA97, TA98, and TA1537
Mouse lymphoma gene mutations	Positive without S9
Sister chromatid exchanges	
Chinese hamster ovary cells *in vivo*:	Positive with or without S9
Chromosomal aberrations	
Chinese hamster ovary cells *in vitro*:	Weakly positive with S9; negative without S9

[a] Denominators of lesions reflect overall rates

EXPLANATION OF LEVELS OF EVIDENCE OF CARCINOGENIC ACTIVITY

The National Toxicology Program describes the results of individual experiments on a chemical agent and notes the strength of the evidence for conclusions regarding each study. Negative results, in which the study animals do not have a greater incidence of neoplasia than control animals, do not necessarily mean that a chemical is not a carcinogen, inasmuch as the experiments are conducted under a limited set of conditions. Positive results demonstrate that a chemical is carcinogenic for laboratory animals under the conditions of the study and indicate that exposure to the chemical has the potential for hazard to humans. Other organizations, such as the International Agency for Research on Cancer, assign a strength of evidence for conclusions based on an examination of all available evidence, including animal studies such as those conducted by the NTP, epidemiologic studies, and estimates of exposure. Thus, the actual determination of risk to humans from chemicals found to be carcinogenic in laboratory animals requires a wider analysis that extends beyond the purview of these studies.

Five categories of evidence of carcinogenic activity are used in the Technical Report series to summarize the strength of the evidence observed in each experiment: two categories for positive results (**clear evidence** and **some evidence**); one category for uncertain findings (**equivocal evidence**); one category for no observable effects (**no evidence**); and one category for experiments that cannot be evaluated because of major flaws (**inadequate study**). These categories of interpretative conclusions were first adopted in June 1983 and then revised in March 1986 for use in the Technical Report series to incorporate more specifically the concept of actual weight of evidence of carcinogenic activity. For each separate experiment (male rats, female rats, male mice, female mice), one of the following five categories is selected to describe the findings. These categories refer to the strength of the experimental evidence and not to potency or mechanism.

- **Clear evidence** of carcinogenic activity is demonstrated by studies that are interpreted as showing a dose-related (i) increase of malignant neoplasms, (ii) increase of a combination of malignant and benign neoplasms, or (iii) marked increase of benign neoplasms if there is an indication from this or other studies of the ability of such tumors to progress to malignancy.
- **Some evidence** of carcinogenic activity is demonstrated by studies that are interpreted as showing a chemically related increased incidence of neoplasms (malignant, benign, or combined) in which the strength of the response is less than that required for clear evidence.
- **Equivocal evidence** of carcinogenic activity is demonstrated by studies that are interpreted as showing a marginal increase of neoplasms that may be chemically related.
- **No evidence** of carcinogenic activity is demonstrated by studies that are interpreted as showing no chemically related increases in malignant or benign neoplasms.
- **Inadequate study** of carcinogenic activity is demonstrated by studies that, because of major qualitative or quantitative limitations, cannot be interpreted as valid for showing either the presence or absence of carcinogenic activity.

When a conclusion statement for a particular experiment is selected, consideration must be given to key factors that would extend the actual boundary of an individual category of evidence. Such consideration should allow for incorporation of scientific experience and current understanding of long-term carcinogenesis studies in laboratory animals, especially for those evaluations that may be on the borderline between two adjacent levels. These considerations should include:

- adequacy of the experimental design and conduct;
- occurrence of common versus uncommon neoplasia;
- progression (or lack thereof) from benign to malignant neoplasia as well as from preneoplastic to neoplastic lesions;
- some benign neoplasms have the capacity to regress but others (of the same morphologic type) progress. At present, it is impossible to identify the difference. Therefore, where progression is known to be a possibility, the most prudent course is to assume that benign neoplasms of those types have the potential to become malignant;
- combining benign and malignant tumor incidence known or thought to represent stages of progression in the same organ or tissue;
- latency in tumor induction;
- multiplicity in site-specific neoplasia;
- metastases;
- supporting information from proliferative lesions (hyperplasia) in the same site of neoplasia or in other experiments (same lesion in another sex or species);
- presence or absence of dose relationships;
- statistical significance of the observed tumor increase;
- concurrent control tumor incidence as well as the historical control rate and variability for a specific neoplasm;
- survival-adjusted analyses and false positive or false negative concerns;
- structure-activity correlations; and
- in some cases, genetic toxicology.

NATIONAL TOXICOLOGY PROGRAM BOARD OF SCIENTIFIC COUNSELORS
TECHNICAL REPORTS REVIEW SUBCOMMITTEE

The members of the Technical Reports Review Subcommittee who evaluated the draft NTP Technical Report on *o*-nitroanisole on November 21, 1991, are listed below. Subcommittee members serve as independent scientists, not as representatives of any institution, company, or governmental agency. In this capacity, subcommittee members have five major responsibilities in reviewing NTP studies:

- to ascertain that all relevant literature data have been adequately cited and interpreted,
- to determine if the design and conditions of the NTP studies were appropriate,
- to ensure that the Technical Report presents the experimental results and conclusions fully and clearly,
- to judge the significance of the experimental results by scientific criteria, and
- to assess the evaluation of the evidence of carcinogenic activity and other observed toxic responses.

SUMMARY OF TECHNICAL REPORTS REVIEW SUBCOMMITTEE COMMENTS

On November 21, 1991, the draft Technical Report on the toxicology and carcinogenesis studies of *o*-nitroanisole received public review by the National Toxicology Program Board of Scientific Counselors Technical Reports Review Subcommittee. The review meeting was held at the National Institute of Environmental Health Sciences, Research Triangle Park, NC.

Dr. R.D. Irwin, NIEHS, introduced the toxicology and carcinogenesis studies of *o*-nitroanisole by discussing the rationale for study, describing the experimental design including additional 2-year stop-exposure studies in rats, reporting on survival and body weight effects, and commenting on compound-related neoplasms in rats and mice and nonneoplastic lesions in rats. The proposed conclusions were *clear evidence of carcinogenic activity* in male and female F344 rats that received diets containing 6,000 or 18,000 ppm for 6 months, *clear evidence of carcinogenic activity* in male $B6C3F_1$ mice, and *some evidence of carcinogenic activity* in female $B6C3F_1$ mice.

Dr. Hayden, a principal reviewer, agreed with the conclusions. He thought the rationale for study could be strengthened by adding a statement on consumer exposure as well as occupational exposure, and by noting that several aromatic amines have been identified as human bladder carcinogens. Dr. Irwin said there were no data on human exposure including the NIOSH National Occupational Exposure Survey.

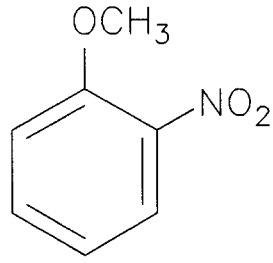
Dr. McKnight, the second principal reviewer, agreed with the conclusions. She said the rationale section should also include mention of why the stop-exposure studies were performed. Dr. Irwin said this would be added. Further, since the conclusions in rats rest heavily on the results of the stop-exposure studies, Dr. McKnight suggested that the appendixes should contain the same level of detail of reporting on individual animal results as that given the usual 2-year studies (Tables E2 and F2).

Dr. Garman, the third principal reviewer, agreed with the conclusions. He said that a statement that absence of renal tubule epithelial cell degeneration in male rats in the high-dose group of the stop-exposure study may have been due to marked reduction in feed consumption should be better elaborated. Dr. Irwin responded that the reduction in feed consumption and body weight was such that the physiology of the animal was altered, leading to an interpretation of an association with diminished renal pathology.

Noting that this was one of the first reports to be considered by the Subcommittee that had both conventional 2-year and stop-exposure study designs, Dr. Klaassen asked for discussion about presentation of design information and results. Dr. Goodman and Mr. Beliczky stated that the results should be considered and reported separately, while Dr. Garman thought they should not be separated, as the stop-exposure study serves to more or less support or confirm the chronic study. Dr. Irwin observed that the stop-exposure study is usually chosen based on the incidence of a lesion with questionable biological behavior at a higher dose level in prechronic studies. In this case, the data from the stop and chronic studies were treated as part of a dose-response and, thus, it was considered appropriate to combine the findings. Dr. S. Eustis, NIEHS, agreed and said that the NTP would prefer not to draw separate conclusions. Dr. Davidson pointed out that the level of evidence in rats would have been less clearcut without the results from the stop-exposure studies. Dr. Goodman said that separation of the statement about mononuclear cell leukemias in rats was appropriate, as the incidences of leukemia in male rats were supportive of *some evidence* and in female rats were supportive of *equivocal evidence*. Dr. Hayden commented that the evidence was supportive of a positive finding for leukemia in both male and female rats but perhaps not as part of *clear evidence*. Dr. Klaassen concluded that there was not a consensus on this issue.

Dr. Hayden moved that the Technical Report on *o*-nitroanisole be accepted with the revisions discussed and with the conclusions as written for male and female rats and male mice, *clear evidence of carcinogenic activity*, and for female mice, *some evidence of carcinogenic activity*. Dr. Garman seconded the motion. Dr. McKnight offered an amendment that mononuclear cell leukemia be listed in the first sentence as part of *clear evidence* in male and female rats. The amendment was tabled for lack of a second. Dr. Hayden's motion was then accepted unanimously with 10 votes.

INTRODUCTION



o-NITROANISOLE

CAS No. 91-23-6

Chemical Formula: $C_7H_7NO_3$ Molecular Weight: 153.13

Synonyms: Methoxynitrobenzene, nitrophenyl methyl ether

PHYSICAL AND CHEMICAL PROPERTIES, PRODUCTION, AND USE

o-Nitroanisole is a colorless to slightly yellow liquid with a boiling point of 277° C, a melting point of 9° to 10° C, and a specific gravity of 1.254. *o*-Nitroanisole is insoluble in water but is soluble in most organic solvents (*Merck Index*, 1983). Two general methods exist for the preparation of *o*-nitroanisole: methylation of *o*-nitrophenol or displacement of chloride from *o*-nitrochlorobenzene by the methoxide ion (NaOH/methanol). *o*-Nitroanisole is used primarily as a precursor to *o*-anisidine which is prepared by direct nitro-reduction. *o*-Anisidine is used extensively in the synthesis of azo dyes either directly after being converted to a diazonium salt or as a precursor for the preparation of dianisidine which is diazotized and coupled. Directly or indirectly, *o*-anisidine is used in the manufacture of over 100 azo dyes.

PHARMACOKINETICS AND METABOLISM

The pharmacokinetics and metabolism of *o*-nitroanisole have been examined in male F344 rats (Miller *et al.*, 1985). Following an intravenous dose of 25 mg/kg, ^{14}C derived from *o*-nitroanisole was rapidly distributed to tissues with the maximum tissue concentrations being reached within 15 minutes after administration. Elimination of ^{14}C from tissues was also rapid and followed a two-component decay. The initial elimination phase was rapid in all tissues and was characterized by a half-life of 1 to 2 hours; however, the terminal elimination phase was slower and varied considerably from tissue to tissue. In plasma, liver, brain, lung, small intestine, and kidney, the terminal elimination half-life was 2.5 days, while that from muscle, blood, spleen, and testes was 4.0, 4.5, 5.2, and 6.2 days, respectively. Elimination of the parent compound (nonradioactive) from the blood was also biphasic with half-lives of 30 minutes and 2.2 hours, while elimination of the parent compound from liver, kidney, and small intestine was monophasic.

Within 24 hours after oral administration of a 5 or 50 mg/kg dose of ^{14}C *o*-nitroanisole, 73% of the 5 mg/kg dose and 69% of the 50 mg/kg dose had been excreted in the urine. Within 7 days after administration, 71% to 78% of the label had been excreted in the urine and 7% in feces. Moreover, the quantity of radioactivity excreted in the bile was similar to the amount found in the feces, indicating that little if any enterohepatic recirculation was occurring. Examination of the urinary metabolites indicated that 63% of the administered dose was present as *o*-nitrophenyl sulfate, 11% as *o*-nitrophenyl glucuronide, 1.5% as *o*-nitrophenol, and 0.6% as *o*-anisidine. This suggests the metabolic

scheme shown in Figure 1, in which *o*-demethylation is the major pathway to form *o*-nitrophenol followed by sulfate or glucuronide conjugation.

Nitroreduction to *o*-anisidine was quantitatively a minor pathway; *o*-anisidine was found only in the liver, and the concentration decayed rapidly and was below the limit of detection within 2 hours after dosing.

CARCINOGENICITY

There are no published studies that have examined the toxicity or carcinogenicity of *o*-nitroanisole. However, *o*-anisidine has been evaluated for carcinogenic potential by the NTP (NCI, 1978b). Groups of 55 F344/N rats received diets containing 5,000 or 10,000 ppm and groups of 55 $B6C3F_1$ mice received diets containing 2,500 or 5,000 ppm *o*-anisidine for 103 weeks. The incidences of transitional cell papillomas or carcinomas of the urinary bladder were significantly increased in all groups of dosed rats (males: 0/51, 52/54, 52/52; females: 0/49, 46/49, 50/51) and in high-dose mice (males: 0/48, 2/55, 22/53; females: 0/50, 1/51, 22/50).

GENETIC TOXICITY

o-Nitroanisole was positive for induction of DNA damage in *Bacillus subtilis* in the absence of S9 (Shimizu and Yano, 1986) and induction of gene mutations in *Salmonella typhimurium* strain TA100, with and without S9 (Table G1; Chiu *et al.*, 1978; Tokiwa *et al.*, 1981; Haworth *et al.*, 1983). It was also reported to be mutagenic in *S. typhimurium* strains TA98 and TA1538 without S9 (Chiu *et al.*, 1978; Shimizu and Yano, 1986). In Chinese hamster ovary cell cultures, *o*-nitroanisole induced sister chromatid exchanges with and without S9 and chromosomal aberrations in the presence of S9 (Tables G3 and G4; Galloway *et al.*, 1987).

Mutagenicity data are available for two metabolites of *o*-nitroanisole, *o*-nitrophenol and *o*-anisidine. *o*-Nitrophenol did not induce gene mutations in *S. typhimurium*, with or without S9 (Chiu *et al.*, 1978; Haworth *et al.*, 1983; Suzuki *et al.*, 1983; Shimizu and Yano, 1986), did not induce DNA damage in *B. subtilis* (Natake *et al.*, 1979; Shimizu and Yano, 1986), and did not induce sex-linked recessive lethal mutations in germ cells of male *Drosophila melanogaster* (NTP, unpublished data).

o-Anisidine, the second metabolite, was genotoxic. It induced gene mutations in *S. typhimurium* in the presence, but not the absence, of S9 (Zeiger *et al.*, 1992), and was mutagenic with and without S9 in mouse lymphoma L5178Y cells (Wangenheim and Bolcsfoldi, 1988). It did not induce sex-linked recessive lethal mutations in *D. melanogaster* (Yoon *et al.*, 1985). Induction of DNA strand breaks was reported in mouse lymphoma L5178Y cells treated with *o*-anisidine in the presence of S9 (Garberg *et al.*, 1988), but tests for induction of DNA repair conducted in male rat hepatocytes without S9 were negative (Yoshimi *et al.*, 1988). *o*-Anisidine induced both sister chromatid exchanges and chromosomal aberrations in Chinese hamster ovary cells with and without S9 (Galloway *et al.*, 1987).

STUDY RATIONALE

o-Nitroanisole was evaluated for carcinogenic potential because of its structural similarity to *o*-anisidine and because human exposure might be associated with its widespread use in the manufacture of azo dyes.

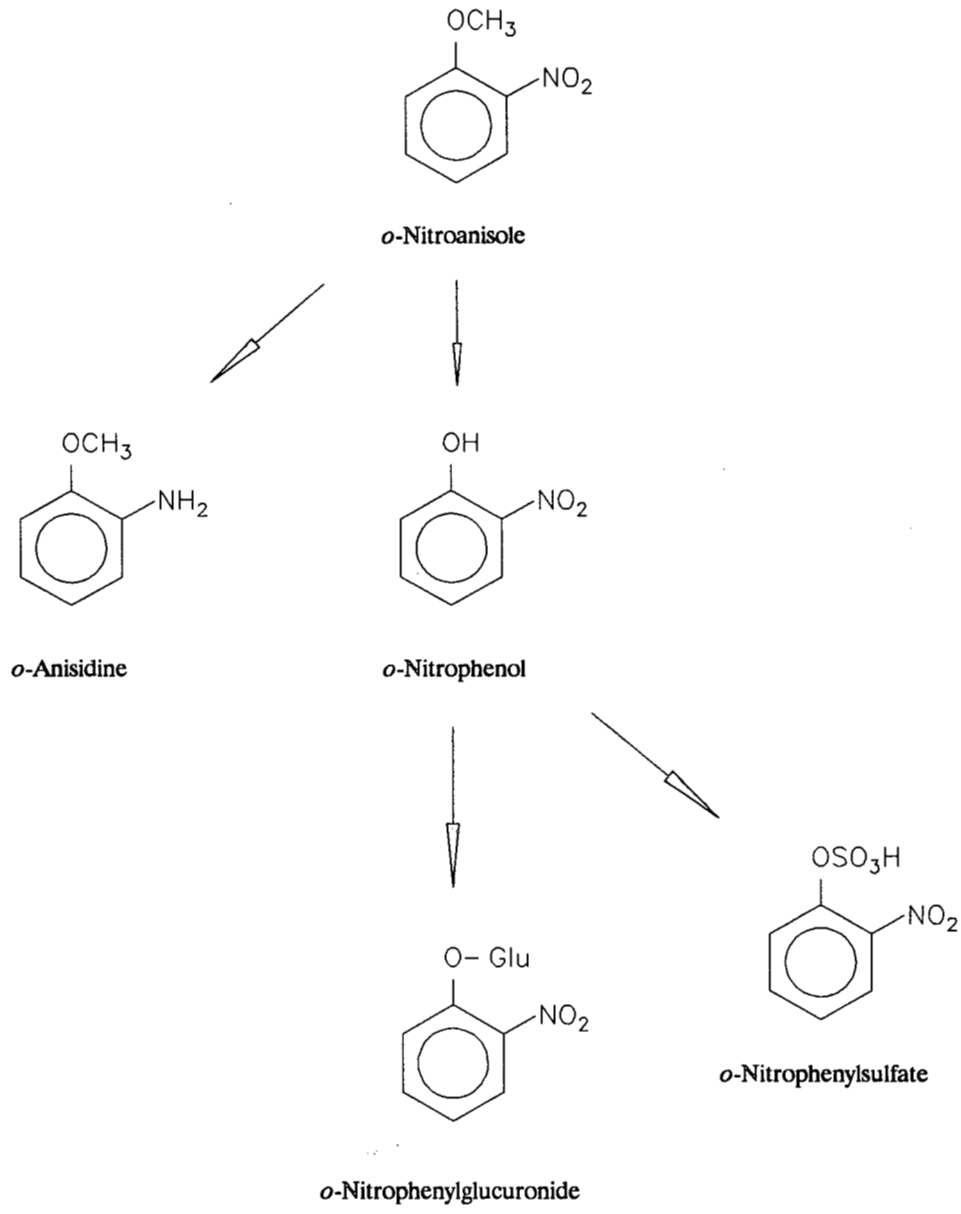


FIGURE 1
The Metabolic Pathway of *o*-Nitroanisole (Miller *et al.*, 1985)

MATERIALS AND METHODS

PROCUREMENT AND CHARACTERIZATION OF *o*-NITROANISOLE

o-Nitroanisole was obtained from the Aldrich Chemical Company (Milwaukee, WI) in three lots (lots TE061197, 2712DL, and 1517AM). Lot TE061197 was used throughout the 14-day and 13-week studies in rats and mice and in portions of the 2-year and stop-exposure studies in rats. Lot 2712DL was used in a portion of the stop-exposure study in rats and portions of the 2-year studies in rats and mice; lot 1517AM was used in a portion of the 2-year studies in rats and mice. Identity, purity, and stability analyses were performed by the analytical chemistry laboratory, Midwest Research Institute (MRI; Kansas City, MO), and confirmed by the study laboratory (Appendix J).

All three lots of the study chemical, a clear yellow liquid, were identified as *o*-nitroanisole by infrared, ultraviolet/visible, and nuclear magnetic resonance spectroscopy. The purity of the lots was found to be greater than 99% by Karl Fischer water analysis, elemental analyses, titration of the nitro group, thin-layer chromatography, and gas chromatography. Stability studies performed at the analytical chemistry laboratory indicated that *o*-nitroanisole was stable as a bulk chemical for 2 weeks at temperatures up to 60° C when stored protected from light. The stability of the bulk chemical was monitored periodically at the study laboratory using infrared and ultraviolet spectroscopy and gas chromatography methods. No change in purity was observed.

PREPARATION AND ANALYSIS OF DOSE FORMULATIONS

The dose formulations were prepared by mixing *o*-nitroanisole and feed in a blender (Table J1). Studies to determine homogeneity and stability of the dosed feed preparations were conducted by the analytical chemistry laboratory. Homogeneity was confirmed using ultraviolet spectroscopy methods for sample analysis. The stability studies of the dose formulations were performed using high performance liquid chromatography (HPLC) methods. These studies indicated that the dose formulations were stable for at least 3 weeks at room temperature and 1 week when stored under simulated animal cage conditions.

Periodic analyses of the dose formulations of *o*-nitroanisole were conducted at the study laboratory and the analytical chemistry laboratory using either ultraviolet spectroscopy or HPLC methods. During the 14-day studies, the dose formulations were analyzed at the beginning of the studies (Table J2). During the 13-week studies, the dose formulations were analyzed at the initiation, midpoint, and end of the studies (Table J3). During the 2-year studies, the dose formulations were analyzed at least once every 8 weeks (Table J4). In the 2-year and stop-exposure studies, 85% (141/166) of the dose formulations were within 10% of the target concentrations. Results of the periodic referee analyses performed by the analytical chemistry laboratory were in good agreement with the results obtained by the study laboratory (Table J5).

14-DAY STUDIES

Male and female F344 rats and B6C3F$_1$ mice were obtained from the Charles River Breeding Facility (Kingston, NY). At receipt, the rats were 4 to 5 weeks old and the mice were 5 to 6 weeks old. The animals were quarantined for 21 days before exposure began. Before the beginning of the studies, five animals of each species and sex were randomly selected for parasite evaluation and gross observation for evidence of disease.

Groups of five male and five female rats were fed diets containing 0, 583, 1,166, 2,332, 4,665, or 9,330 ppm *o*-nitroanisole; groups of five male and five female mice were fed diets containing 0, 250, 500, 1,000, 2,000, or 4,000 ppm *o*-nitroanisole. The appropriate feed was supplied weekly and was available *ad libitum*. Animals were housed five per cage and water was available *ad libitum*. Clinical findings were recorded twice daily. Feed consumption was recorded weekly by cage. The animals were weighed at study initiation, at day 7,

and at the end of the studies. Details of study design and animal maintenance are summarized in Table 1.

At the end of the 14-day studies, blood and urine were collected from all male rats for clinical pathology analyses. The clinical pathology parameters measured are listed in Table 1. A gross necropsy was performed on all rats and mice. The brain, heart, right kidney, liver, lungs, right testis, thymus, and trachea were weighed from rats and mice. Histopathologic examinations were not conducted.

13-Week Studies

The 13-week studies were conducted to evaluate the cumulative toxic effects of repeated exposure to *o*-nitroanisole and to determine the appropriate doses to be used in the 2-year studies.

Male and female F344 rats and B6C3F$_1$ mice were obtained from the Charles River Breeding Facility (Portage, MI). Upon receipt, the rats were 4 to 5 weeks old and the mice were 5 to 6 weeks old. The animals were quarantined for 9 days before exposure began. Before the beginning of the studies, five animals of each species and sex were randomly selected for parasite evaluation and gross observation for evidence of disease. At the end of the studies, serologic analyses were performed on five control animals of each species and sex using the protocols of the NTP Sentinel Animal Program (Appendix M).

Groups of 10 male and 10 female rats were fed diets containing 0, 200, 600, 2,000, 6,000, or 18,000 ppm *o*-nitroanisole; groups of 10 male and 10 female mice were fed diets containing 0, 60, 200, 600, 2,000, or 6,000 ppm *o*-nitroanisole. The appropriate feed was supplied weekly and was available *ad libitum*. Animals were housed five per cage; water was available *ad libitum*. Clinical findings were recorded twice daily. Feed consumption was recorded weekly by cage. The animals were weighed at the beginning of the studies and weekly thereafter. Further details of study design and animal maintenance are summarized in Table 1.

At the end of the 13-week studies, blood and urine were collected from all animals for clinical pathology analyses. The clinical pathology parameters measured are listed in Table 1. A necropsy was performed on all animals. The brain, heart, right kidney, liver, lungs, spleen, right testis, and thymus were weighed. Tissues for microscopic examination were embedded in paraffin, sectioned to a thickness of 4 to 6 μm, and stained with hematoxylin and eosin. A complete histopathologic examination was performed on all control animals, all animals that received 6,000 ppm, and all animals dying early. The epididymis, kidney, liver, spleen, testis, and urinary bladder of all exposed rats were examined microscopically. Table 1 lists the tissues and organs routinely examined microscopically.

2-Year Studies

Study Design

In the core study, groups of 60 male and 60 female rats were fed diets containing 0, 222, 666, or 2,000 ppm *o*-nitroanisole; groups of 60 male and 60 female mice were fed diets containing 0, 666, 2,000, or 6,000 ppm *o*-nitroanisole for 103 weeks. Up to 10 rats and mice per group were designated for interim evaluations after 15 months of chemical administration.

The stop-exposure study consisted of groups of 60 male and 60 female rats fed diets of 0, 6,000, or 18,000 ppm *o*-nitroanisole for 27 weeks and then held up to an additional 77 weeks without further treatment. Ten rats per group were scheduled for interim evaluations after 3, 6, 9, and 15 months.

Source and Specification of Animals

Male and female F344 rats and B6C3F$_1$ mice were obtained from Simonsen Laboratories (Gilroy, CA) for use in the 2-year studies. Rats were quarantined for 11 days, and mice were quarantined for 10 days before the beginning of the studies. Five rats and five mice of each sex were selected for parasite evaluation and gross observation of disease. Serology samples were collected for viral screening. Rats and mice in the 2-year studies were approximately 40 days old at the beginning of the studies; rats in the stop-exposure study were approximately 41 days old at the beginning of the study. The health of the animals was monitored during the studies according to the NTP Sentinel Animal Program (Appendix M).

Animal Maintenance

Rats were housed five per cage; mice were housed individually. Feed and water were available *ad libitum*. Cages were rotated every 2 weeks during the studies. Further details of animal maintenance

are given in Table 1. Information on feed composition is provided in Appendix L.

Clinical Examinations and Pathology

All animals were observed twice daily. Clinical findings were recorded weekly for the first 13 weeks, and monthly thereafter. Animals were weighed at study initiation, weekly for the first 13 weeks, and monthly thereafter. Up to 10 rats and mice were selected from each group in the 2-year studies for interim evaluations at 15 months. During the stop-exposure study, up to 10 rats from each group were selected for interim evaluations after 3, 6, 9, and 15 months. All animals received a complete gross examination. The brain, right kidney, liver, spleen, and right testis were weighed at the 15-month interim evaluations in the 2-year studies.

Animals found in a moribund state or surviving to the end of the 2-year studies received a complete necropsy. At necropsy, all organs and tissues were examined for gross lesions, and all major tissues were fixed and preserved in 10% neutral buffered formalin, processed and trimmed, embedded in paraffin, sectioned, and stained with hematoxylin and eosin for microscopic examination. Histopathologic examinations were performed on all tissues with grossly visible lesions. Tissues examined are listed in Table 1.

Microscopic evaluations were completed by the study laboratory pathologist and the pathology data were entered into the Toxicology Data Management System. The microscopic slides, paraffin blocks, and residual wet tissues were sent to the NTP Archives for inventory, slide/block match, and wet tissue audit. The slides, individual animal data records, and pathology tables were evaluated by an independent quality assessment laboratory. The individual animal records and tables were compared for accuracy, slide and tissue counts were verified, and histotechnique was evaluated. For the 2-year studies in rats, a quality assessment pathologist reviewed the forestomach, kidney, large intestine (stop-exposure study), liver, pancreas (male), spleen, uterus (stop-exposure study), and urinary bladder for accuracy and consistency of diagnosis. In the 2-year study in mice, a quality assessment pathologist reviewed the liver, nose, lung, and lymphoid tissues.

The quality assessment report and slides were submitted to the NTP Pathology Working Group (PWG) chair, who reviewed the selected tissues for which there was a disagreement in diagnosis between the laboratory and quality assessment pathologists. Representative histopathology slides containing examples of lesions related to chemical administration, examples of disagreements in diagnosis between the laboratory and quality assessment pathologists, or lesions of general interest were presented by the chair to the PWG for review. The PWG consisted of the quality assessment pathologist and other pathologists experienced in rodent toxicologic pathology. This group examined tissues without knowledge of exposure group or previously rendered diagnoses. When the consensus opinion of the PWG differed from that of the laboratory pathologist, the final diagnosis was changed. Details of these review procedures have been described, in part, by Maronpot and Boorman (1982) and Boorman *et al.* (1985). For subsequent analysis of pathology data, the diagnosed lesions for each tissue type were evaluated separately or combined according to the guidelines of McConnell *et al.* (1986).

Statistical Methods

Survival Analyses

The probability of survival was estimated by the product-limit procedure of Kaplan and Meier (1958) and is presented in the form of graphs. Animals were censored from the survival analyses at the time they were found dead of other than natural causes or were found to be missing; animals dying from natural causes were not censored. Statistical analyses for possible dose-related effects on survival used Cox's (1972) method for testing two groups for equality and Tarone's (1975) life table test to identify dose-related trends. All reported P values for the survival analysis are two sided.

Calculation of Incidence

The incidences of neoplasms or nonneoplastic lesions as presented in Tables A1, A5, B1, B5, C1, C5, D1, D5, E1, E4, F1, and F4 are given as the number of animals bearing such lesions at a specific anatomic site and the number of animals with that site examined microscopically. For calculation of statistical significance, the incidences of most neoplasms (Tables A3, B3, C3, D3, E3, and F3) and all nonneoplastic lesions are given as the ratio of the number of affected animals to the number of animals with the site examined microscopically. However, when macroscopic examination was required to detect neoplasms in certain tissues (e.g., skin or mammary

gland) before microscopic evaluation, or when neoplasms had multiple potential sites of occurrence (e.g., mononuclear cell leukemia), the denominators consist of the number of animals on which a necropsy was performed.

Analysis of Neoplasm Incidence

The majority of neoplasms in these studies were considered to be incidental to the cause of death or not rapidly lethal. Thus, the primary statistical method used was logistic regression analysis, which assumed that the diagnosed neoplasms were discovered as the result of death from an unrelated cause and thus did not affect the risk of death. In this approach, neoplasm prevalence was modeled as a logistic function of chemical exposure and time. Both linear and quadratic terms in time were incorporated initially, and the quadratic term was eliminated if it did not significantly enhance the fit of the model. The neoplasm incidences of exposed and control groups were compared on the basis of the likelihood score test for the regression coefficient of dose. This method of adjusting for intercurrent mortality is the prevalence analysis of Dinse and Lagakos (1983), further described and illustrated by Dinse and Haseman (1986). When neoplasms are incidental, this comparison of the time-specific neoplasm prevalences also provides a comparison of the time-specific neoplasm incidences (McKnight and Crowley, 1984).

In addition to logistic regression, alternative methods of statistical analysis were used, and the results of these tests are summarized in the appendixes. These include the life table test (Cox, 1972; Tarone, 1975), appropriate for rapidly lethal neoplasms, and the Fisher exact test and the Cochran-Armitage trend test (Armitage, 1971; Gart *et al.*, 1979), procedures based on the overall proportion of neoplasm-bearing animals.

Tests of significance include pairwise comparisons of each exposed group with controls and a test for an overall dose-response trend. Continuity-corrected tests were used in the analysis of neoplasm incidence, and reported P values are one sided. The procedures described above also were used to evaluate selected nonneoplastic lesions. For further discussion of these statistical methods, see Haseman (1984).

Historical Control Data

Although the concurrent control group is always the first and most appropriate control group used for evaluation, there are certain instances in which historical control data can be helpful in the overall assessment of neoplasm incidence. Consequently, control neoplasm incidences from the NTP historical control database (Haseman *et al.*, 1984, 1985) are included in the NTP reports for neoplasms appearing to show compound-related effects.

Analysis of Continuous Variables

Two approaches were employed to assess the significance of pairwise comparisons between exposed and control groups in the analysis of continuous variables. Organ and body weight data, which have approximately normal distributions, were analyzed using the parametric multiple comparison procedures of Williams (1971, 1972) and Dunnett (1955). Hematology, clinical chemistry, and urinalysis data, which have typically skewed distributions, were analyzed using the nonparametric multiple comparison methods of Shirley (1977) and Dunn (1964). Jonckheere's test (Jonckheere, 1954) was used to assess the significance of the dose-response trends and to determine whether a trend-sensitive test (Williams' or Shirley's test) was more appropriate for pairwise comparisons than a test that does not assume a monotonic dose-response trend (Dunnett's or Dunn's test). Average severity values were analyzed for significance using the Mann-Whitney U test (Hollander and Wolfe, 1973).

Quality Assurance Methods

The 13-week and 2-year studies were conducted in compliance with Food and Drug Administration Good Laboratory Practice Regulations (21 CFR, Part 58). In addition, as records from the 2-year studies were submitted to the NTP Archives, they were audited retrospectively by an independent quality assurance contractor. Separate audits covering completeness and accuracy of the pathology data, pathology specimens, final pathology tables, and preliminary review draft of this NTP Technical Report were conducted. Audit procedures and findings are presented in the reports and are on file at NIEHS. The audit findings were reviewed and assessed by NTP staff so all had been resolved or were otherwise addressed during the preparation of this Technical Report.

GENETIC TOXICOLOGY

The genetic toxicity of *o*-nitroanisole was assessed by testing its ability to induce mutations in *Salmonella typhimurium*, sister chromatid exchanges and chromosomal aberrations in Chinese hamster ovary cells, and trifluorothymidine resistance in mouse L5178Y lymphoma cells. The protocols and results of these studies are given in Appendix G.

Histopathology			
None	Complete histopathologic examinations were performed on all control rats and mice, all rats and mice that received 6,000 ppm, and all rats and mice that died early. In addition to tissue masses, gross lesions, and associated lymph nodes, the tissues examined included: adrenal gland, colon (rats), clitoral gland (rats), epididymis, eye, heart (rats), kidney, liver, lung and mainstem bronchi, mammary gland (mice), mandibular lymph node (rats), nose (rats), ovary, parathyroid gland, pituitary gland (rats), preputial gland (rats), rectum (rats), salivary gland, seminal vesicle, skin (mice), spleen (rats), testis, thymus, thyroid gland, trachea (rats), urinary bladder, uterus (rats), and vagina (mice). In addition, the epididymis, kidney, liver, spleen, testis, and urinary bladder of all exposed rats were examined microscopically.	At the interim evaluations and the terminal sacrifice, kidney, liver, spleen, testis (including epididymis), urinary bladder, ureter, uterus, and gross lesions were examined microscopically in all exposed groups.	Complete histopathologic examinations were performed on all control, high-dose, and early death rats, all mice, and all rats and mice at the 15-month interim evaluations. In addition to tissue masses, gross lesions, and associated lymph nodes, the tissues examined included: adrenal gland, bone (including marrow), brain, clitoral gland, coagulating gland, ear (male rats), epididymis, esophagus, eye, gallbladder (mice), harderian gland, heart, kidney, lacrimal gland (female rats), large intestine (cecum, colon, rectum), liver, lung, lymph node (mandibular and mesenteric), mammary gland, mesentery, nose, ovary, pancreas, parathyroid gland, penis (mice), pharynx (rats), pituitary gland, preputial gland, prostate gland, salivary gland, seminal vesicle, skeletal muscle, skin, small intestine (duodenum, jejunum, ileum), spleen,

Histopathology (continued)			
			stomach (forestomach and glandular), testis, thymus, thyroid gland, tongue (females), tooth (mice and male rats), trachea, urinary bladder, uterus, vagina, and Zymbal's gland (female rats). The clitoral gland, epididymis, kidney, liver, preputial gland, spleen, testis, urinary bladder, and uterus of all rats receiving 222 and 666 ppm were examined microscopically.

RESULTS

Rats

14-Day Study

All rats survived until the end of the study (Table 2). The mean body weight gains of males receiving 4,665 and 9,330 ppm and the final mean body weight of males receiving 9,330 ppm were significantly lower than those of the controls. Mean body weight gains and final mean body weights of all exposed females were similar to those of the controls. Feed consumption by male and female rats administered *o*-nitroanisole was similar to that by the controls. Dietary levels of 583, 1,166, 2,332, 4,665, and 9,330 ppm resulted in average daily consumption levels of 48, 106, 209, 435, and 881 mg/kg for males and 48, 93, 197, 387, and 787 mg/kg for females.

Erythrocyte counts, hematocrit values, and hemoglobin concentrations in all exposed male groups were significantly lower than those in controls (Table I1). Reticulocyte counts and methemoglobin concentrations were significantly increased in males receiving 1,166 ppm or more, and Heinz bodies were present in erythrocytes from 9,330 ppm males.

At the end of the study, the relative brain, kidney, liver, and testis weights of males and the relative kidney and liver weights of females in the 9,330 ppm groups were significantly greater than those of the controls (Table H1). Because the absolute brain, kidney, and testis weights were not significantly increased in exposed groups, the increased relative organ weights were attributed primarily to the lower final mean body weights of the 9,330 ppm groups. However, the significantly increased absolute liver weights of males that received 1,166 ppm and of females that received 583 ppm or more *o*-nitroanisole were considered related to chemical administration.

13-WEEK STUDY

All rats survived until the end of the study, except one female receiving 2,000 ppm that died during week 5 (Table 3). Mean body weight gains and final mean body weights of males and females receiving 6,000 and 18,000 ppm were significantly lower than those of controls. The final mean body weight of 18,000 ppm males was 52% lower than that of the controls, while the final mean body weight of 18,000 ppm females was 36% lower than that of the controls. Final mean body weights of males and females receiving 6,000 ppm were 14% lower than those of the controls. Feed consumption by rats receiving 18,000 ppm was substantially less than that by controls throughout the study, whereas feed consumption by the 6,000 ppm groups was only slightly less than that by controls (Table 4). The reduced feed consumption may have been due to decreased palatability. Dietary levels of 200, 600, 2,000, 6,000, and 18,000 ppm resulted in average daily consumption levels of 10, 30, 100, 300, and 720 mg/kg for males and females.

Hemoglobin and hematocrit values in male and female rats receiving 2,000, 6,000, and 18,000 ppm were significantly lower than those in controls (Table I2). Erythrocyte counts were significantly lower primarily in males and females receiving 6,000 and 18,000 ppm. These differences were accompanied by increases in the mean values for nucleated erythrocytes, reticulocytes, methemoglobin, and total leukocyte counts. Heinz bodies were observed frequently in the erythrocytes of all rats receiving 18,000 ppm and in some rats receiving 6,000 ppm. These findings are consistent with a mild, regenerative anemia resulting from an increased formation of methemoglobin. Methemoglobin is formed by the oxidation of bound iron in hemoglobin from the Fe^{2+} to the Fe^{3+} oxidation state followed by irreversible denaturation of the globin portion of hemoglobin eventually leading to the formation of Heinz bodies, which are aggregates of denatured hemoglobin. Heinz body formation is often associated with premature erythrocyte destruction due to extravascular or intravascular hemolysis.

[a] Feed consumption is expressed as grams/animal per day.

Urine samples collected from rats receiving 2,000 ppm or more were dark yellow or amber-colored, whereas those of control rats were light yellow or straw-colored. The slightly darker color of the urine from exposed rats is probably due to increased excretion of hemoglobin or bilirubin metabolites rather than increased urine concentration since the specific gravity of urine from exposed animals was similar to that of the controls (Table I2).

The absolute and relative liver weights of all exposed male and female rat groups were significantly greater than those of the controls, with the exception of the absolute liver weight of 18,000 ppm males (Table H2). The absolute and relative kidney weights of males receiving 600, 2,000, and 6,000 ppm and the relative kidney weight of males receiving 18,000 ppm were significantly greater than those of the controls. In females, the relative kidney weights were significantly increased in the 6,000 and 18,000 ppm groups, but the absolute kidney weights of exposed female groups and controls were similar. The increases in absolute and relative liver and kidney weights were attributed to *o*-nitroanisole.

The absolute and relative spleen weights of male and female rats receiving 6,000 and 18,000 ppm were also significantly increased, which is consistent with the histologic lesions observed in the spleen. The absolute and relative thymus weights of female rats and the absolute thymus weight of male rats that received 18,000 ppm were significantly decreased. It is uncertain if this finding is due to a direct effect of *o*-nitroanisole on the thymus, or if the thymus is more sensitive than other organs to the nutritional effects associated with decreased feed consumption. The thymus is particularly sensitive to the effects of stress and debilitation associated with a variety of causes and becomes atrophic. Differences in the absolute or relative testis, heart, and lung weights of rats receiving 6,000 and 18,000 ppm were associated with the lower final mean body weights and are not believed to be the result of specific organ toxicity.

The principal lesions associated with the administration of *o*-nitroanisole to rats for 13 weeks were observed in the urinary bladder, spleen, kidney, liver, testis, and uterus as described below.

Urinary bladder: Diffuse hyperplasia of the transitional epithelium of the urinary bladder was seen in all rats receiving 6,000 and 18,000 ppm (Table 5). The hyperplasia generally was more severe in females than in males and more severe in the 18,000 ppm groups than in the 6,000 ppm groups. Focal squamous metaplasia frequently accompanied the hyperplasia, particularly in females. The transitional epithelium of exposed rats was thickened and formed rugose or papillary folds. In rats that received 18,000 ppm, the transitional epithelium was often greater than 30 cell layers thick, whereas that of controls was usually less than five cell layers thick. The foci of squamous metaplasia consisted of moderate to well-differentiated squamous epithelium with abundant eosinophilic cytoplasm, prominent intercellular bridges, and an overlying layer of keratin.

A transitional cell papilloma of the urinary bladder was seen in one male, transitional cell carcinomas were seen in two males and three females, and a squamous cell carcinoma was seen in one female, all in the 18,000 ppm groups. The neoplasms were seen in areas of diffuse hyperplasia. The papilloma consisted of thick branching folds of transitional epithelium, and differed from the more severe hyperplastic lesions primarily by the extent and complexity of branching. The transitional cell carcinomas were also exophytic nodular or rugose masses, but the markedly thickened epithelium consisted of anaplastic, pleomorphic cells. The squamous cell carcinoma consisted of an area of squamous differentiation with interconnecting cords and small clusters of pleomorphic squamous cells infiltrating the submucosa.

Spleen: The splenic red pulp of many males in the 18,000 ppm group and females in the 6,000 and 18,000 ppm groups contained increased numbers of erythrocytes (congestion), which probably accounts for the significantly increased absolute and relative spleen weights of these groups (Table 5). The congestion was associated with increased numbers of macrophages containing hemosiderin pigment. All rats receiving 18,000 ppm and several receiving 6,000 ppm had foci of capsular fibrosis with infiltrations of erythrocytes, hematopoietic cells, and mononuclear inflammatory cells which were diagnosed as capsular hyperplasia (Plate 1). In addition, all rats that received 18,000 ppm had mild to moderate depletion of lymphocytes from the periarteriolar lymphocytic sheaths and lymphoid follicles.

Since the spleen is a major site for the removal of senescent or damaged erythrocytes from the circulation, the congestion and accumulation of hemosiderin-laden macrophages in the spleen are frequently associated with hemolytic anemia and methemoglobinemia. The capsular hyperplasia is frequently seen in enlarged spleens due to a variety of causes, and may be the result of small ruptures in the delicate capsular connective tissue. The precise cause of the lymphoid depletion in the spleen is uncertain, but lymphoid depletion at various sites such as the thymus, lymph nodes, and spleen often accompanies reductions in body weight, and thus may not be a direct effect of *o*-nitroanisole.

Liver: Generalized centrilobular and midzonal hepatocyte hypertrophy was seen in all rats receiving 18,000 ppm. The affected hepatocytes were enlarged and had more homogeneous, eosinophilic cytoplasm than did unaffected cells in the centrilobular region. The livers of all rats that received 18,000 ppm also had scattered Kupffer cells filled with a granular, golden brown pigment, believed to be hemosiderin.

[a] Number of animals necropsied
[b] Number of animals with lesions
[c] Average severity grade of lesions in affected animals: 1 = slight, 2 = minimal, 3 = mild, 4 = moderate, 5 = severe.

Kidney: Multifocal degeneration, necrosis, or both, of the renal tubule epithelium with infiltration of mononuclear inflammatory cells and formation of tubular casts occurred in male rats receiving 600, 2,000, and 6,000 ppm (Plates 2 and 3), but not in those receiving 18,000 ppm or in exposed female rats (Table 5). The reduced nutrient and chemical intake associated with the lower feed consumption may account for the absence of these lesions in the 18,000 ppm group. Granular, golden brown pigment, believed to be hemosiderin, was observed in scattered epithelial cells in the proximal convoluted tubules of males receiving 18,000 ppm and females receiving 6,000 and 18,000 ppm.

Testis: All male rats that received 18,000 ppm exhibited degeneration of the seminiferous epithelium characterized by necrosis and loss of spermatogenic cells, decreased numbers of spermatozoa, and accumulations of necrotic debris and multinucleated cells in the seminiferous tubules (Table 5).

Uterus: Uterine atrophy was observed in all female rats receiving 18,000 ppm and in a few females receiving 2,000 and 6,000 ppm (Table 5). The affected uteri were smaller than those of the controls and the endometrial and myometrial cells had less abundant cytoplasm.

Dose selection rationale: The lower final mean body weights and reduced feed consumption observed in males and females that received diets containing 6,000 and 18,000 ppm *o*-nitroanisole suggest poor feed palatability. In addition, the severity of regenerative anemia associated with methemoglobin formation was significantly increased in males and females receiving 6,000 and 18,000 ppm. Consequently, these concentrations were considered too high for continuous dietary administration in a 2-year study. At 2,000 ppm, final mean body weights and feed consumption were similar to controls and the anemia was minimal. Therefore, 2,000 ppm was considered an acceptable high concentration for the 2-year study. The remaining concentrations selected were 222 and 666 ppm, since 222 ppm was a no-effect level and at 666 ppm only minimal signs of anemia were present.

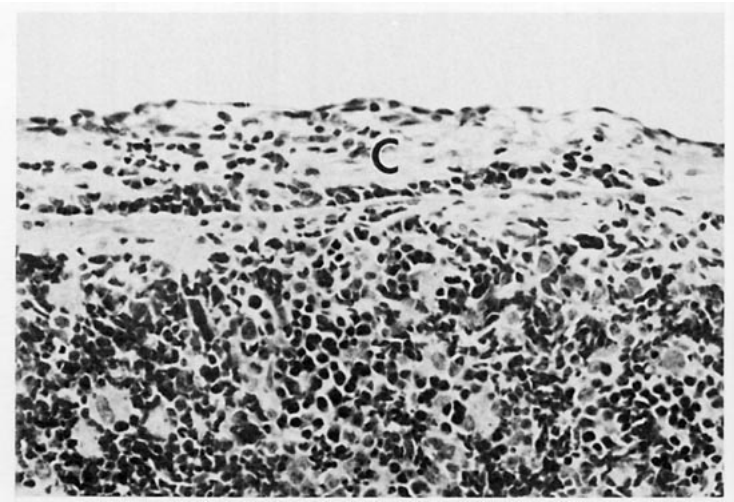

PLATE 1
Spleen: The splenic capsule (C) is thickened by accumulated mononuclear cells and delicate fibrous tissue. Male rat given 18,000 ppm *o*-nitroanisole in the 13-week feed study. H&E ×100

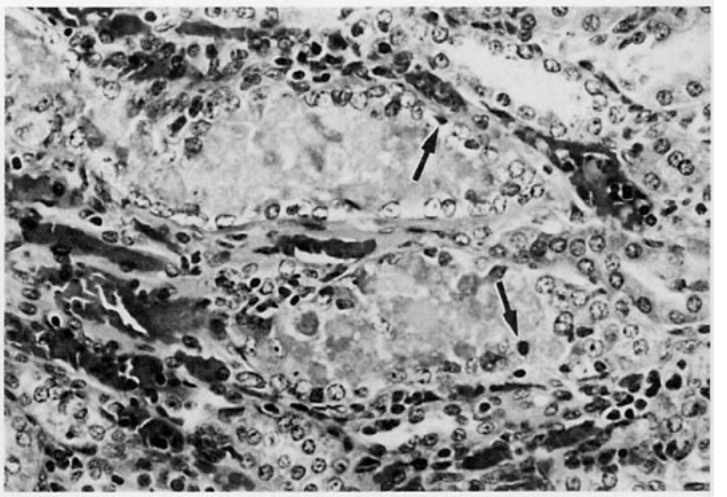

PLATE 2
Kidney: Note the renal tubule distended with cellular debris, the attenuated epithelium, and the occasional necrotic epithelial cells with pyknotic nuclei (arrows). Male rat given 6,000 ppm *o*-nitroanisole in the 13-week feed study. H&E ×100

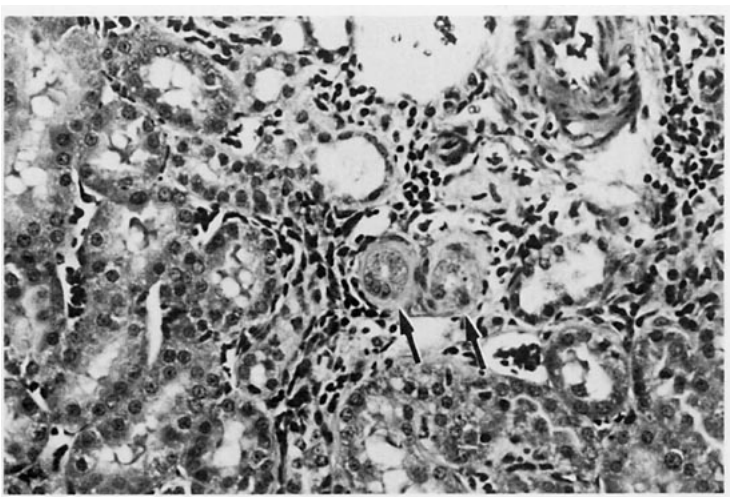

PLATE 3
Kidney: Mild nephropathy. Note the interstitial mononuclear cell infiltrate, tubules with thickened basement membrane (arrows), and slightly dilated tubules lined by attenuated epithelium. Male rat given 6,000 ppm *o*-nitroanisole in the 13-week feed study. H&E ×80

2-YEAR STUDY

Survival

Estimates of survival probabilities for male and female rats are shown in Table 6 and in the Kaplan-Meier curves in Figure 2. Survival of 2,000 ppm male rats was significantly lower than that of the controls. Survival of 666 ppm males was slightly lower than that of the controls, but the difference was not significant by the life table analysis. The reduced survival of 666 and 2,000 ppm males was primarily attributed to the increased numbers of animals with severe renal disease (nephropathy) and associated secondary hyperparathyroidism. Survival of males receiving 222 ppm and of all exposed females was similar to the controls.

[b] Includes one animal that died during the last week of the study
[c] Kaplan-Meier determinations
[d] Mean of all deaths (uncensored, censored, and terminal sacrifice).
[e] The result of the life table trend test (Tarone, 1975) is in the control column, and the results of the life table pairwise comparisons (Cox, 1972) with the controls are in the dosed columns. A lower mortality in a dose group is indicated by N.

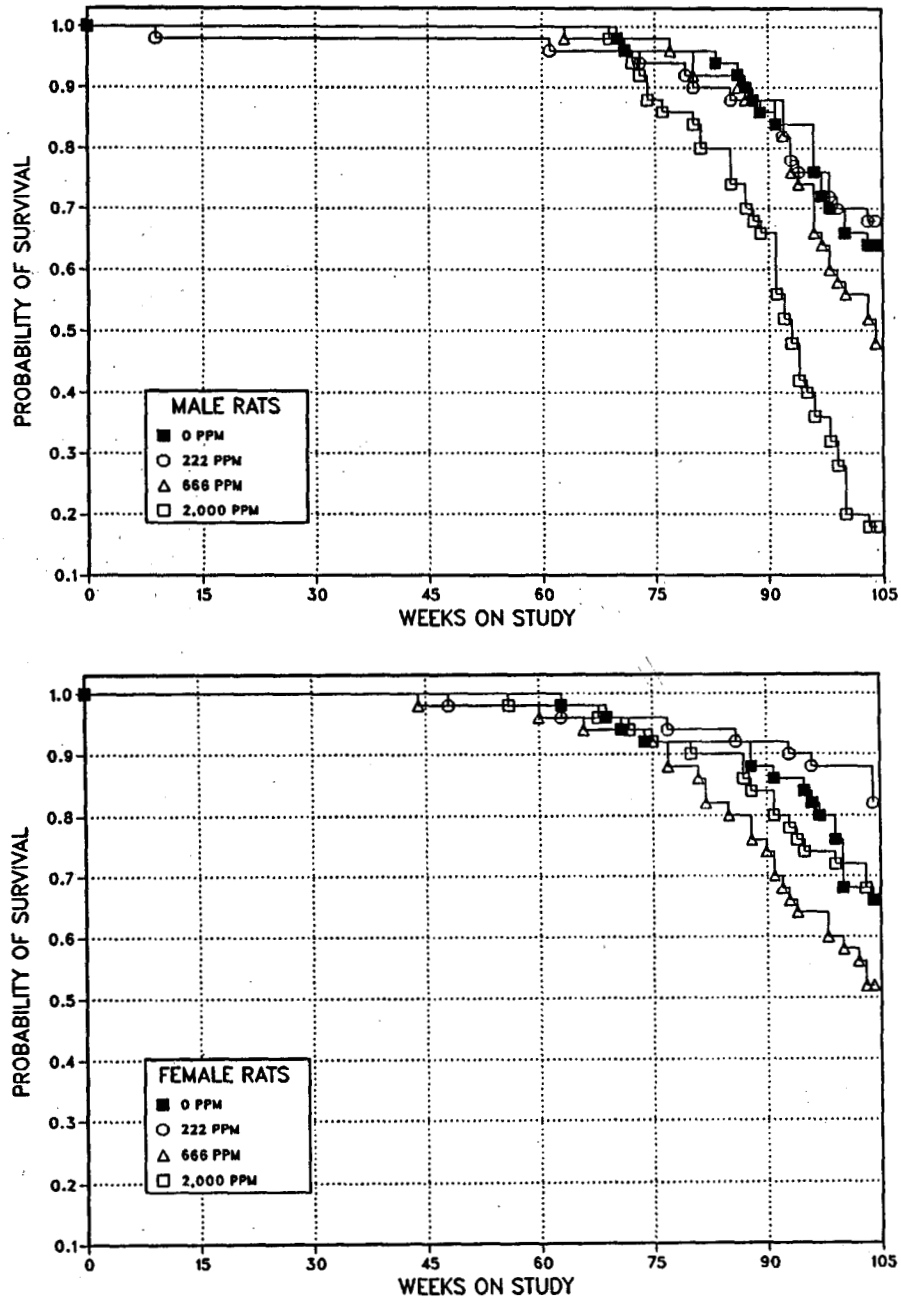

FIGURE 2
Kaplan-Meier Survival Curves for Male and Female Rats Administered *o*-Nitroanisole in Feed for 2 Years

Body Weights, Feed Consumption, and Clinical Findings

Mean body weights of male and female rats that received 2,000 ppm were lower than those of controls (Tables 7 and 8). The mean body weights of 2,000 ppm male rats were within 5% of the controls until week 72 (Table 7 and Figure 3). Thereafter, the difference in mean body weight between males receiving 2,000 ppm and the controls gradually increased; the final mean body weight of males receiving 2,000 ppm was 16% lower than that of the controls. The mean body weights of 2,000 ppm female rats were within 5% of the controls until week 48, but the difference gradually increased; the final mean body weight of 2,000 ppm females was 9% lower than that of the controls (Table 8 and Figure 3). The mean body weights of male and female rats that received 222 and 666 ppm were within 5% of the controls throughout the 2-year study. Feed consumption by exposed male and female rats was similar to that by the controls throughout the study (Tables K1 and K2). Dietary levels of 222, 666, and 2,000 ppm resulted in average daily consumption levels of 10, 30, and 80 mg/kg for males and 10, 30, and 90 mg/kg for females. There were no clinical findings associated with *o*-nitroanisole administration.

Pathology and Statistical Analyses of Results

Summaries of the incidences of nonneoplastic lesions and neoplasms, the individual animal tumor diagnoses, the statistical analyses of primary neoplasms that occurred with an incidence of at least 5% in at least one group, and historical control incidences for the biologically significant neoplasms mentioned in this section are presented in Appendix A for male rats and Appendix B for female rats.

Hematopoietic system: The incidences of mononuclear cell leukemia in males receiving 666 or 2,000 ppm and females receiving 2,000 ppm were significantly increased (Tables 9, A3, and B3). However, the incidence of mononuclear cell leukemia in 2,000 ppm males was slightly lower than in 666 ppm males, possibly due to the reduced survival in the 2,000 ppm group. The incidences of mononuclear cell leukemia in males receiving 666 or 2,000 ppm and females receiving 2,000 ppm also exceed the range for NTP historical controls (males: 32%-62%; females: 14%-36%; Tables A4a and B4a). Although incidences of mononuclear cell leukemia were increased, the mean time to observation (neoplasm latency) was not substantially reduced in the exposed groups (males: 0 ppm, 694 days; 222 ppm, 695 days; 666 ppm, 688 days; and 2,000 ppm, 638 days; females: 685, 701, 650, and 686 days).

Mononuclear cell leukemia was characterized by the proliferation of polymorphic mononuclear cells with hyperchromatic nuclei in the splenic sinusoids. In more advanced stages, this leukemia involved the interfollicular red pulp completely. As the disease progressed, infiltrates of mononuclear leukemia cells occurred in the liver, lung, kidney, lymph nodes, and other organs. In male rats with mononuclear cell leukemia, organs other than the spleen and liver were more frequently affected in the 666 and 2,000 ppm groups than in the control group. In female rats, the disease was generally limited to the spleen and liver.

Kidney: The relative kidney weight of males that received 2,000 ppm was significantly greater than that of the controls at the 15-month interim evaluation (Table H3). There was a corresponding slight increase in the absolute kidney weight of this group, even though the mean body weight of the 2,000 ppm group was substantially lower than that of the controls. Chronic nephropathy occurred in all male rats, and the severity of the disease increased in a dose-related manner at the 15-month interim evaluation and at the end of the 2-year study (Tables 10 and A5). In female rats, there was little evidence of a chemical-related effect on the kidney. Absolute and relative kidney weights of exposed female groups were similar to those of controls at the 15-month interim evaluation (Table H3). Although the incidences of nephropathy were marginally increased in the exposed female groups, the increased incidences were not significant and were not dose related (Tables 10 and B5). However, the proportion of female rats with moderate nephropathy was greater in the 2,000 ppm group than in the controls.

Nephropathy in rats was characterized by a spectrum of degenerative and inflammatory changes including degeneration and atrophy of the tubule epithelium with the formation of granular and hyaline casts in the tubule lumens, regeneration of the tubule epithelium, thickening of the glomerulus and tubule basement membranes, interstitial fibrosis, and infiltrates of mononuclear inflammatory cells. The severity of nephropathy was graded based on the extent of involvement as follows: minimal, less than 25%; mild, 25% to 50%; moderate, 50% to 75%; and marked, greater than 75%.

[a] Number of neoplasm-bearing animals/number of animals examined microscopically
[b] 2-Year historical incidence for control groups in NTP feed study (mean ± standard deviation): 385/800 (48.1% ± 7.7%); range 32%-62%
[c] Kaplan-Meier estimated neoplasm incidence at the end of the study after adjustment for intercurrent mortality
[d] Observed incidence at terminal kill
[e] Beneath the control incidence are the P values associated with the trend test. Beneath the dosed group incidence are the P values corresponding to pairwise comparisons between the controls and that dosed group. The life table analysis regards neoplasms in animals dying prior to terminal kill as being (directly or indirectly) the cause of death. The logistic regression tests regard these lesions as nonfatal. For both tests, a lower incidence in a dose group is indicated by N.
[f] Historical incidence: 213/800 (26.6% ± 8.8%); range 14%-36%

Focal hyperplasia of the renal tubule was seen in three males receiving 222 ppm and two males receiving 2,000 ppm, but not in male rats receiving 666 ppm or in the controls (Table A5). Renal tubule adenomas were also seen in one male each from the 222, 666, and 2,000 ppm groups, and renal tubule carcinomas occurred in two additional males that received 2,000 ppm (Table A1). The incidence of adenoma or carcinoma (combined) occurred with a significant positive trend in male rats, and the incidence in the 2,000 ppm group was significantly greater than that in the controls (Table A3). The incidence of renal tubule neoplasms in NTP historical control male rats is 11 of 798 (1%) with a range of 0% to 6% (Table A4d). Thus, it is uncertain if the small number of renal tubule neoplasms in the exposed groups is related to *o*-nitroanisole exposure.

Focal hyperplasia, adenoma, and carcinoma of the renal tubule epithelium constitute a morphological continuum. Focal hyperplasia was considered a preneoplastic lesion and was differentiated from the epithelial regeneration which commonly accompanies nephropathy. It was characterized by one or several cross sections of a single tubule with two or more layers of epithelial cells partially or completely filling the tubule lumen. The adenomas were circumscribed solid masses, generally larger than five tubule diameters, consisting of polygonal epithelial cells with mild atypia. The carcinomas were substantially larger than the adenomas and exhibited heterogenous growth patterns, cellular pleomorphism, and cytologic atypia.

Liver: The absolute liver weights of males receiving 2,000 ppm and females receiving 666 and 2,000 ppm were significantly greater than those of the controls at the 15-month evaluation (Table H3). The chemical-related increase in absolute liver weights was accompanied by significant increases in relative liver weights of male and female rats that received 666 and 2,000 ppm. Despite the increased liver weights, there were no lesions of the liver that occurred more frequently in exposed rats than in controls at the 15-month interim evaluation (Tables 11, A5, and B5). However, the incidences of basophilic foci in males and females receiving 2,000 ppm and of clear cell foci in males receiving 2,000 ppm were lower than those in controls.

In the 2-year study, several nonneoplastic lesions occurred more frequently in exposed rats than in controls (Tables 11, A5, and B5). The incidence of focal cystic degeneration, also called spongiosis hepatis, was significantly increased in males that received 2,000 ppm. The lesion was characterized by small multilocular spaces distorting the hepatic cords and containing finely granular or flocculent material and occasional erythrocytes. The lesion is believed to constitute a degenerative process involving the fat storing cell (Ito cell). The incidence of eosinophilic foci occurred with a significant positive trend in exposed male rats and the incidences in all exposed groups were significantly greater than that in the controls. An eosinophilic focus is one of several different forms of cellular alteration occurring in the liver and is characterized by changes in staining quality of the hepatocyte cytoplasm. Eosinophilic foci were well circumscribed and slightly compressed the surrounding parenchyma. There was some irregularity of the hepatic cords, but they blended in with normal hepatic cords at the periphery. The cells were often slightly enlarged and the cytoplasm was homogeneous and eosinophilic. The incidence of focal hyperplasia of the bile ducts in the portal areas of the liver lobules was significantly increased in female rats receiving 2,000 ppm. The incidence of nodular hyperplasia was significantly increased in males that received 666 and 2,000 ppm and in females that received 2,000 ppm. Nodular hyperplasia generally occurred in the liver of rats with mononuclear cell leukemia and consisted of poorly circumscribed foci of hypertrophic hepatocytes. Nodular hyperplasia was considered to represent a regenerative response to the degenerative changes in the liver that commonly accompany mononuclear cell leukemia.

The incidences of basophilic foci in the 666 and 2,000 ppm groups of males and the 2,000 ppm group of females were significantly lower than those in controls. Similarly the incidences of clear cell foci in males receiving 666 and 2,000 ppm were significantly lower than that in controls. Basophilic focus is the most common spontaneously occurring form of cellular alteration in the liver of F344 rats, whereas clear cell focus occurs much less frequently. It is uncertain to what extent the decreased incidences of basophilic

and clear cell foci are directly related to the ingestion of *o*-nitroanisole or to the increased incidences of mononuclear cell leukemia in the exposed groups. The leukemic infiltrates produce substantial degenerative changes in the liver which might obscure or affect the occurrence of spontaneous foci of cellular alteration.

Hepatocellular adenomas occurred in three males receiving 222 ppm, one male receiving 666 ppm, and two males and three females receiving 2,000 ppm (Tables A1 and B1). A hepatocellular carcinoma was seen in one additional male that received 222 ppm. Although no hepatocellular neoplasms were seen in control males, the incidences in the exposed males did not increase with dose and were not significantly increased (Table A3). The incidence of hepatocellular adenoma in female rats occurred with a significant positive trend, but the incidence in the 2,000 ppm group was not significantly greater than that in the controls (Table B3). In NTP historical controls, hepatocellular neoplasms have occurred in 24 of 799 (3%) male and 4 of 800 (0.5%) female rats (Tables A4b and B4b). The few hepatocellular neoplasms in exposed rats are not believed to be chemical related.

Urinary bladder: Focal hyperplasia of the transitional epithelium of the urinary bladder occurred in one female that received 222 ppm and two males and six females that received 2,000 ppm (Tables A5 and B5). Moreover, a transitional cell papilloma was seen in one female from the 2,000 ppm group and a transitional cell carcinoma was seen in another female from the same group (Table B1). Transitional cell neoplasms of the urinary bladder are rare spontaneous neoplasms and have occurred in 2 of 790 historical control female F344/N rats. These neoplasms are described further in the results of the stop-exposure study.

Stomach: The incidence of ulcers of the forestomach mucosa was significantly increased in male rats receiving 2,000 ppm (Tables 12 and A5). There were corresponding increased incidences of edema and chronic inflammation that were associated with the ulcers. There was a slightly but not significantly increased incidence of ulcers in females that received 2,000 ppm (Tables 12 and B5). The incidence of focal hyperplasia of the forestomach epithelium increased with exposure level in male and female rats, and the incidences in all exposed male groups and in females from the 2,000 ppm group were significantly increased. Squamous cell papillomas or carcinomas occurred in several groups of exposed males and females, but none were observed in controls (Tables A1 and B1). Squamous cell papillomas were seen in one female receiving 222 ppm, one male receiving 666 ppm, and one male and one female receiving 2,000 ppm. Squamous cell carcinomas were seen in one male receiving 666 ppm and one male and one female receiving 2,000 ppm. Although these neoplasms occurred at very low incidences, they are rare spontaneous neoplasms in F344 rats. In NTP historical controls, squamous cell papillomas have occurred in 2 of 800 males and 1 of 800 females; squamous cell carcinomas have occurred in 1 of 800 males and none have occurred in females (Tables A4c and B4c).

Focal hyperplasia and papillomas of the forestomach squamous epithelium constitute a morphological continuum. Focal hyperplasia was characterized by increased cellularity and thickening of the epithelium with the formation of rugose folds and simple blunt papillae. The papillomas were distinguished from hyperplasia on the basis of complexity of structure. The squamous cell papillomas were short stalks with branching papillae consisting of well-differentiated stratified epithelium overlying a delicate fibrovascular stroma. The squamous cell carcinomas invaded the forestomach mucosa with cords and clusters of anaplastic cells.

Lung: Hyperplasia of the alveolar epithelium occurred at a low incidence in all exposed female groups, but did not occur in controls (Table B5). In addition, alveolar/bronchiolar adenomas were seen in two females that received 666 ppm and three females that received 2,000 ppm, and a squamous cell carcinoma of the lung was seen in another female that received 2,000 ppm (Table B1). Alveolar/bronchiolar neoplasms have occurred in 17 of 800 (2%, range 0%-10%) historical control females. Because of the small number of pulmonary neoplasms, they are not believed to be chemical related. In male rats the incidences of alveolar/bronchiolar neoplasms were similar in control and exposed groups (Table A1).

Pituitary gland: At the 15-month interim evaluation, adenomas of the pars distalis were seen in three

control males and one male receiving 222 ppm; none were observed in males receiving 2,000 ppm (Table A1). At the end of the 2-year study, the incidence of adenomas of the pars distalis occurred with a significant negative trend in exposed male rats, and the incidence in the 2,000 ppm group was significantly decreased (14/50, 11/50, 9/49, 4/49; Table A3). Carcinomas occurred in one control male and one male that received 666 ppm (Table A1). The incidence of focal hyperplasia of the pars distalis in males did not decrease with dose and was highest in the 666 ppm group (3/50, 9/50, 11/49, 5/49; Table A5).

Mammary gland: The incidence of fibroadenoma of the mammary gland was marginally decreased in females receiving 2,000 ppm (17/50, 18/50, 15/50, 9/50; Table B3). Although the trend test was signifi cant, the incidence of fibroadenoma in the 2,000 ppm group was not significantly lower than that in the control. Thus, the marginal decrease was not considered chemical related.

STOP-EXPOSURE STUDY

Survival

Estimates of survival probabilities for male and female rats are shown in Table 13 and in the Kaplan-Meier curves in Figure 4. Four males and four females in the 18,000 ppm groups scheduled for evaluation at 9 months, all males and females in the 18,000 ppm groups scheduled for evaluation at 15 months, and seven males in the 6,000 ppm group scheduled for evaluation at 15 months died before the evaluation periods. One male and two females in the control groups scheduled for evaluation at 15 months also died early. All early death animals were included with the core study animals for evaluation. In the stop-exposure core study, all males and females receiving 18,000 ppm had died or were killed moribund by week 48 (males) or week 61 (females). In the 6,000 ppm groups, all but one male and four females died or were killed moribund before the end of the study. Nearly all exposed rats that died early had urinary bladder neoplasms, which presumably was the major contributing cause of death.

Body Weights, Feed Consumption, and Clinical Findings

The final mean body weights of exposed male and female rats were significantly lower than those of the controls (Tables 14 and 15, and Figure 5). Feed consumption by exposed males and females was lower than that by the controls for the first year of the study (Tables K3 and K4). However, by the end of the study feed consumption by male and female exposed groups was similar to that by the controls. Dietary levels of 6,000 and 18,000 ppm resulted in average daily consumption levels of 340 and 1,100 mg/kg for males and females. The only clinical finding related to chemical administration in male and female rats was the presence of discolored urine.

Pathology and Statistical Analyses of Results

Summaries of the incidences of nonneoplastic lesions and neoplasms, the individual animal tumor diagnoses, and the statistical analyses of primary neoplasms that occurred with an incidence of at least 5% in at least one group are presented in Appendix E for male rats and Appendix F for female rats. Because of the extensive mortality in the exposed groups, logistic regression analyses had greatly reduced power and are not included here.

Urinary bladder: The urinary bladder was the primary organ in which neoplasms developed in rats following the ingestion of *o*-nitroanisole at dietary concentrations of 6,000 or 18,000 ppm for up to 6 months followed by a normal diet. At the 3-, 6-, and 9-month interim evaluations the absolute and relative urinary bladder weights of male and female rats receiving 18,000 ppm were significantly greater than those of the controls (Tables H4, H5, and H6).

At the 3-month interim evaluation, the principal lesions observed in the urinary bladder were similar to those observed at the same dietary concentrations in the 13-week study (Tables 16, E4, and F4). Diffuse hyperplasia of the transitional epithelium was seen in nearly all male and female rats that received 18,000 ppm and in 8 of 10 female rats that received 6,000 ppm. The transitional epithelium was irregularly thickened with many folds and blunt papillae separated by extensions of the basement membrane. Although the epithelium of controls was approximately 3 to 10 cell layers thick depending on the degree of bladder contraction (Plates 4 and 5), the epithelium of rats receiving 18,000 ppm was generally more than 30 cell layers thick (Plates 6 and 7). The size and staining properties of the epithelial cells in each bladder varied from populations of small basophilic cells to populations of larger, more typical transitional cells with eosinophilic cytoplasm. Focal or multifocal squamous metaplasia was also seen in all males and females in the 18,000 ppm groups. The squamous cells were well differentiated with prominent keratin layers on the surface (Plate 8). In one male receiving 18,000 ppm, the markedly thickened transitional epithelium exhibited sufficient focal cellular pleomorphism and atypia to be diagnosed as a carcinoma (Table 16). Subacute inflammation and proliferation of connective tissue in the lamina propria accompanied the epithelial changes described above in most males and females that received 18,000 ppm (Plate 9). They were characterized by scattered inflammatory cells, principally neutrophils and macrophages, and increased numbers of fibroblasts with immature collagen.

By 6 months, transitional cell carcinomas were present in all rats receiving 18,000 ppm (Tables 16, E1, and F1). The proliferation of the transitional epithelium in these rats was extensive enough to form exophytic nodular masses with heterogeneous growth

[d] All males and females receiving 18,000 ppm died before the 15-month interim evaluation.
[e] Includes a leiomyosarcoma in one 6,000 ppm and two 18,000 ppm females and a fibrosarcoma in one 18,000 ppm female.

patterns and pleomorphic cell populations (Plates 10, 11, and 12). Foci of squamous differentiation were observed in all neoplasms. Diffuse hyperplasia of the transitional epithelium was present in all males and females that received 6,000 ppm, and papillomas were observed in two males that received 6,000 ppm.

Malignant mesenchymal neoplasms (sarcomas) were present in two males receiving 18,000 ppm. The sarcomas appeared to originate in the lamina propria and were characterized by the proliferation of anaplastic fusiform cells with elongated oval nuclei and scant cytoplasm. In contrast to the connective tissue proliferation seen in most males and females in the 18,000 ppm groups and some rats in the 6,000 ppm groups, the sarcomas were more localized and extensive and consisted of undifferentiated cells with little collagen production. Subacute inflammation was also observed in exposed rats.

At 9 months, only six males and six females in the 18,000 ppm groups were still alive; all had transitional cell carcinomas, one male had a squamous cell carcinoma (Plate 13), and two females had sarcomas (Table 16 and Plate 14). Hyperplasia was seen in nearly all males and females receiving 6,000 ppm. Transitional cell carcinomas were seen in three males and two females, and transitional cell papillomas were present in two males from the 6,000 ppm groups.

By 15 months, all males and females that received 18,000 ppm and 7 of 10 males that received 6,000 ppm had died. Transitional cell carcinomas were seen in 9 of 10 females receiving 6,000 ppm and a papilloma was seen in the other female from this group (Table 16).

Of the core group rats in the stop-exposure study, transitional cell carcinomas were seen in nearly all exposed male and female rats (Table 16). Of the males and females receiving 6,000 ppm that were without carcinomas, three males and one female had transitional cell papillomas. Moreover, squamous cell carcinomas were seen in five males and one female that received 18,000 ppm and squamous cell papillomas were seen in four males and four females that received 18,000 ppm. Sarcomas were seen in 7 males and 12 females receiving 18,000 ppm and in 1 male and 2 females receiving 6,000 ppm. Neoplasms arising from the urinary bladder epithelium were not observed in control rats. Inflammation and connective tissue proliferation in the lamina propria, similar to those seen at the interim evaluations, were also observed in many exposed rats. Two females from the 18,000 ppm group and three females from the 6,000 ppm group also exhibited focal proliferation of well-differentiated lipocytes (adipocytes or fat cells) in the lamina propria (Table F4). Since fat cells are not normally found in the lamina propria, the formation of these cells was considered a metaplastic process.

Large intestine: In the stop-exposure study, the intestines were examined at necropsy. Histologic sections were prepared and examined microscopically only when a lesion or mass was observed. Neoplasms of the large intestine, principally adenomatous polyps, were observed in small numbers of exposed rats at the 6-, 9-, and 15-month interim evaluations (Tables 17, E1, and F1). At the end of the stop-exposure study, however, the incidences of adenomatous polyps in exposed groups of males and females were significantly increased. In addition, four males and two females receiving 18,000 ppm had carcinomas of the large intestine. The neoplasms were polypoid masses in the colon, cecum, or rectum, and multiple neoplasms were observed in some animals. The adenomatous polyps consisted of a moderately well-differentiated columnar epithelium forming coiled tubular glands which were separated by a delicate fibrovascular stroma (Plate 15). The few carcinomas exhibited invasion of the stalk by anaplastic epithelial cells (Plate 16) with an accompanying proliferation of fibrous connective tissue (scirrhous reaction).

Kidney: Any potential chemical-related effect on absolute kidney weights was obscured by the more overt changes associated with the body weight differences between control and exposed groups. Relative kidney weights of most males and females receiving 6,000 and 18,000 ppm were significantly greater than those of the controls at the 3-, 6-, 9-, and 15-month interim evaluations (Tables H4, H5, H6, and H7). Absolute kidney weights of males and females that received 18,000 ppm were significantly lower than those of the controls at 3 and 6 months.

Hydronephrosis (dilatation of the renal pelvis) was observed in two exposed male rats at the 9-month interim evaluation and in many exposed male and female rats at the end of the stop-exposure study (Tables 18, E4, and F4). This was observed in rats

[d] All males and females receiving 18,000 ppm died before the 15-month interim evaluation.

with transitional cell neoplasms of the urinary bladder and was considered a secondary partial obstruction of urine outflow. There was an increase in the incidence or severity of pigmentation in exposed rats at the various interim evaluations and at the end of the stop-exposure study. The pigment, located in scattered epithelial cells of the proximal tubules, was believed to be primarily hemosiderin derived from the breakdown of erythrocytes.

Nephropathy occurred in most of the males in the exposed and control groups. However, the average severity of nephropathy in exposed males was greater than that in controls at 3 and 6 months (Table 18).

At the 9- and 15-month interim evaluations, the effect was still evident in the 6,000 ppm group, even though the dietary administration of *o*-nitroanisole had ceased at week 27. The apparent lack of an effect in males receiving 18,000 ppm at 9 months may have been the result of reduced feed consumption, lower body weight, or both. *o*-Nitroanisole had no effect on the incidence or severity of nephropathy in female rats at any of the interim evaluations. At the end of the stop-exposure study, the incidences or severity of nephropathy in males and females that received 18,000 ppm were decreased and may have been related to the decreased survival, lower body weights, and reduced feed consumption of these groups.

Hyperplasia of the transitional epithelium (urothelium) lining the renal pelvis was observed in some males and females that received 18,000 ppm at 6 months, some males and females that received 6,000 and 18,000 ppm at 9 months, and some males that received 6,000 ppm at 15 months. At the end of the stop-exposure study, the incidence of hyperplasia was significantly increased in all exposed groups of males and females. In addition, papillomas of the transitional epithelium were seen in three males and one female receiving 18,000 ppm, while carcinomas were seen in one male receiving 6,000 ppm and six males and one female receiving 18,000 ppm (Plate 17); none were observed in the controls (Tables 18, E1, and F1). Neoplasms arising from the transitional epithelium of the renal pelvis are extremely rare in NTP historical controls; none have been seen in the current historical control database (male, 0/798; female, 0/797).

Liver: At the 3- and 6-month interim evaluations, the absolute liver weights of males and females that received 6,000 ppm and females that received 18,000 ppm were significantly greater than those of the controls (Tables H4 and H5). In addition, the relative liver weights of males and females in all exposed groups were significantly greater than those of the controls. The absolute liver weight of males in the 18,000 ppm group was similar to that of controls, despite the substantially lower mean body weight. At 9 and 15 months, any potential chemical-related effect on liver weights was partially obscured by the effects on body weight. However, the relative liver weights of males and females receiving 6,000 ppm and females receiving 18,000 ppm were significantly increased at 9 months, and that of females receiving 6,000 ppm was significantly increased at 15 months (Tables H6 and H7).

The lesions observed in the livers of exposed rats are consistent with the differences in absolute and relative liver weights noted above (Tables 19, E4, and F4). Generalized centrilobular hypertrophy was observed at 3 and 6 months in all males and females that received 18,000 ppm. Focal hepatocellular necrosis, consisting of scattered individual or small clusters of cells in the centrilobular regions, was also seen in all males and females receiving 18,000 ppm at 3 months and at 6 months (Plate 18). Multifocal hepatocellular cytoplasmic vacuolation was seen in several males and females in the 18,000 ppm groups at 3 months, and a dose-related increased incidence of this lesion was seen in male rats at 6 months. There were no chemical-related increased incidences of hypertrophy, necrosis, or cytoplasmic vacuolation at 9 or 15 months.

Accumulation of golden or greenish brown pigment in scattered Kupffer cells was seen in all males and females receiving 18,000 ppm at 3 and 6 months, and in all but one male and all females receiving 18,000 ppm at 9 months (Table 19). Similar pigment-filled Kupffer cells were not seen in the controls. In the core groups of the stop-exposure study, pigment-filled Kupffer cells were also seen in most males and all females that received 18,000 ppm. In addition, a number of control females had similar pigment while none was observed in the control males. The pigment had staining properties consistent with hemosiderin.

[c] Average severity grade of lesions in affected animals: 1 = minimal, 2 = mild, 3 = moderate, 4 = marked.
[d] All males and female receiving 18,000 ppm died before the 15-month interim evaluation.

Spleen: Relative spleen weights of exposed male and female rats were significantly greater than those of controls at 3 and 6 months (Tables H4 and H5). At 3 months, the absolute spleen weights of all exposed males and females were significantly increased; there were significant increases in the absolute spleen weights of all exposed female groups and of males receiving 18,000 ppm at 6 months. At the 9-month interim evaluation, the absolute spleen weights of male and female rats receiving 18,000 ppm and the relative spleen weights of all exposed male groups and of females receiving 18,000 ppm remained significantly increased (Table H6). The chemical-related increases in relative spleen weights were associated with the splenic congestion observed histologically. The red pulp of nearly all exposed rats at the 3-, 6-, and 9-month interim evaluations contained increased numbers of erythrocytes (Tables 20, E4, and F4). The congestion was generally more severe in the 18,000 ppm groups than in the 6,000 ppm groups. In the core groups of the stop-exposure study, the incidence of congestion in males that received 18,000 ppm was significantly increased, reflecting the large number of males in the 18,000 ppm group which died early.

Testis: At 3 and 6 months the absolute and relative testis weights of males receiving 18,000 ppm were significantly lower than those of the controls, while the relative testis weight of males receiving 6,000 ppm was significantly greater than that of controls (Tables H4 and H5). At 9 months the findings were similar, except that the relative testis weight of the 18,000 ppm group was significantly greater than that of controls (Table H6). These differences may be due to the chemical-related lower mean body weights of the exposed males which would largely obscure any direct effect of *o*-nitroanisole on testis weight.

Degeneration and atrophy of the seminiferous epithelium of the testes were observed at the 3- and 6-month interim evaluations in most males that received 18,000 ppm, while at 9 months only three of the six males that received 18,000 ppm exhibited atrophy (Table E4). The lesions were generally mild to moderate at 3 and 6 months and minimal at 9 months. The lesions were characterized by the degeneration and loss of spermatogenic cells, decreased numbers of mature spermatozoa, and the presence of cellular debris and multinucleated cells in the tubule lumens (Plates 19 and 20). At the end of the stop-exposure study, atrophy associated with aging or with interstitial cell neoplasms was seen in most control males, and the incidences of atrophy in the exposed groups were lower than in the controls. This decreased incidence was largely due to the early deaths of exposed rats, which precluded the development of interstitial cell neoplasms and aging changes.

Uterus: The absolute uterine weights of exposed females were significantly lower than those of the controls at 3 and 6 months, while at 9 months only that of the 18,000 ppm group was significantly lower (Tables H4, H5 and H6). Although relative uterine weights were not affected at 3 and 9 months, those of the exposed groups at 6 months were significantly lower than that of the controls. Again, it is difficult to determine if the differences in uterine weight were caused, in part, by *o*-nitroanisole because of the marked chemical-related reduction in mean body weights in the exposed groups.

Uterine atrophy was observed microscopically in all exposed females at 3 and 6 months, and in 3 of 6 females receiving 18,000 ppm at 9 months (Table F4). In general, the uteri of females in the 6,000 ppm group were less severely affected than those in the 18,000 ppm group. Histologically, the atrophy was characterized by reduced thickness of the endometrium and myometrium, and reduced amounts of cytoplasm in the affected cells, as compared with controls.

Urinary Bladder: Note the proliferation of delicate fibrous connective tissue beneath the hyperplastic transitional epithelium. Male rat given 18,000 ppm *o*-nitroanisole at the 3-month interim evaluation of the stop-exposure feed study. H&E ×50

PLATE 10
Urinary Bladder: This carcinoma of the transitional epithelium is primarily exophytic but there is early invasion of the submucosa (arrow; see Plate 11). Female rat given 18,000 ppm *o*-nitroanisole at the 6-month interim evaluation of the stop-exposure feed study. H&E ×10

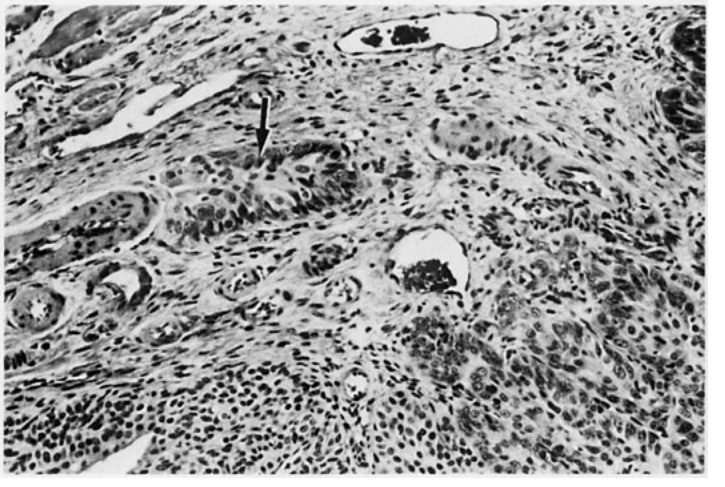

PLATE 11
Urinary Bladder: Higher magnification of Plate 10. This is the base of the carcinoma and shows anaplastic epithelial cells with clusters of cells extending into the submucosa (arrow). Female rat given 18,000 ppm *o*-nitroanisole at the 6-month interim evaluation of the stop-exposure feed study. H&E ×50

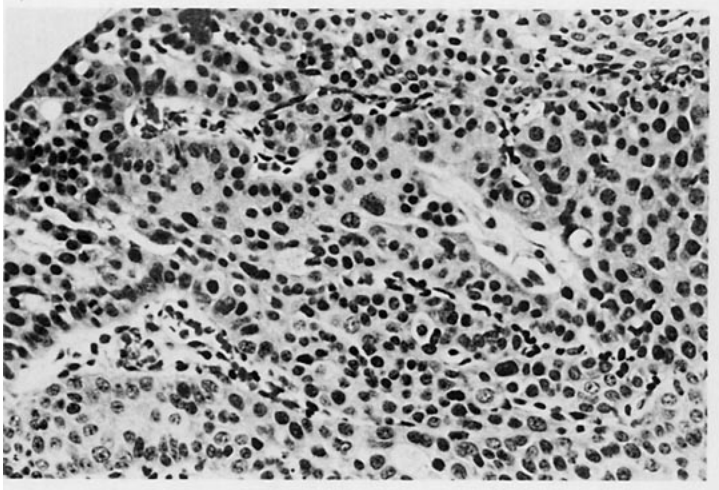

PLATE 12
Urinary Bladder: Higher magnification of Plate 10. The main body of the carcinoma consists of cords and clusters of transitional epithelial cells separated by a delicate fibrovascular stroma. There is mild pleomorphism of the neoplastic cells. Female rat given 18,000 ppm *o*-nitroanisole at the 6-month interim evaluation of the stop-exposure feed study. H&E ×80

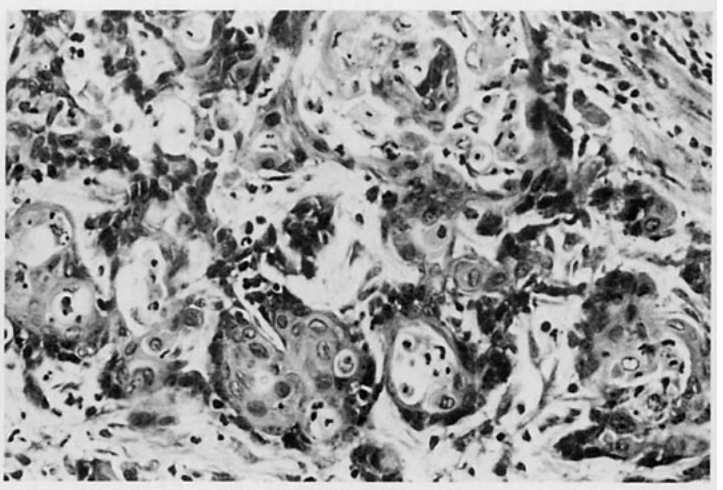

PLATE 13
Urinary Bladder: Squamous cell carcinoma with irregular cords and clusters of anaplastic squamous cells invading the bladder wall. Male rat given 18,000 ppm *o*-nitroanisole at the 9-month interim evaluation of the stop-exposure feed study. H&E ×80

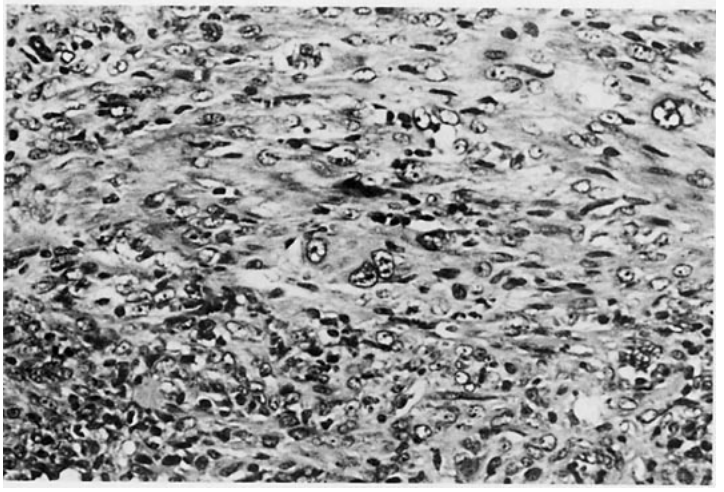

PLATE 14
Urinary Bladder: Sarcoma consisting of pleomorphic spindle cells with variable amounts of fibrillar cytoplasm and intercellular collagen. Male rat given 18,000 ppm *o*-nitroanisole at the 9-month interim evaluation of the stop-exposure feed study. H&E ×80

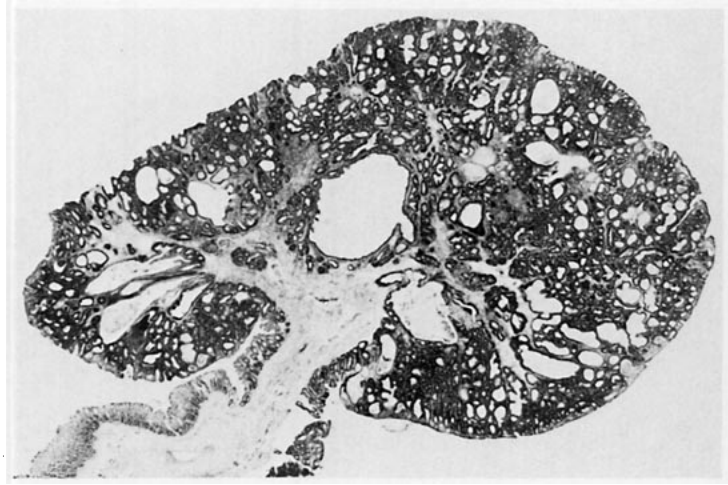

PLATE 15
Colon: Adenomatous polyp in a female rat given 18,000 ppm *o*-nitroanisole at the 9-month interim evaluation of the stop-exposure feed study. H&E ×10

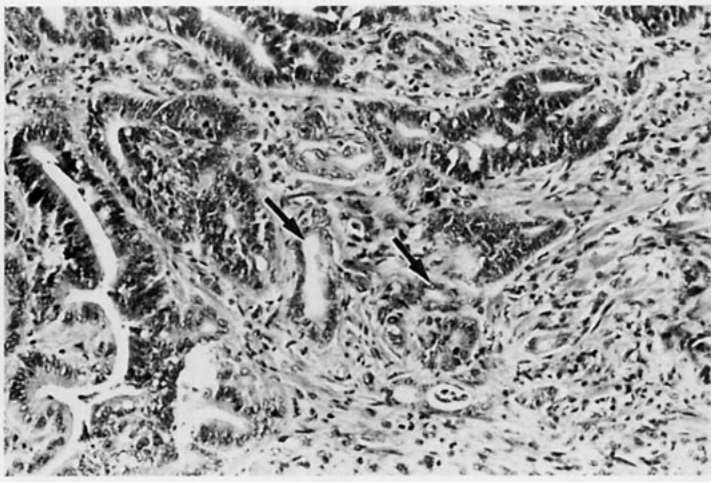

PLATE 16
Large Intestine: Carcinoma with gland-like tubules consisting of anaplastic epithelium (arrows). Male rat given 18,000 ppm *o*-nitroanisole at the 9-month interim evaluation of the stop-exposure feed study. H&E ×50

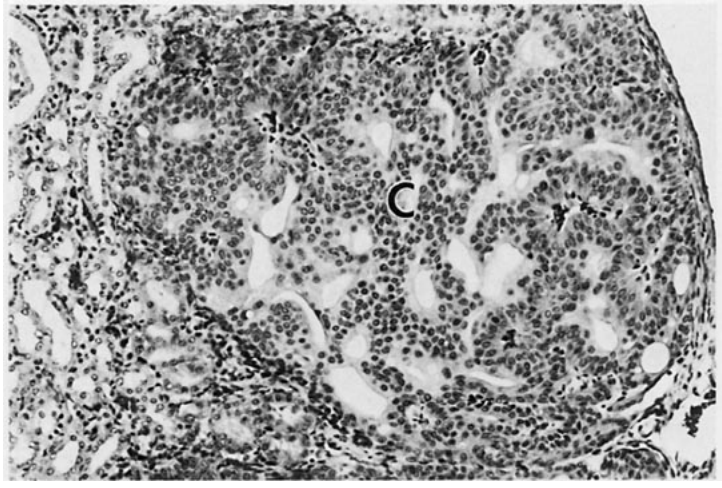

PLATE 17
Kidney: Carcinoma (C) of the pelvic urothelium (transitional epithelium) consisting of interconnecting cords of epithelial cells invading the kidney. Male rat given 18,000 ppm *o*-nitroanisole at the 9-month interim evaluation of the stop-exposure feed study. H&E ×40

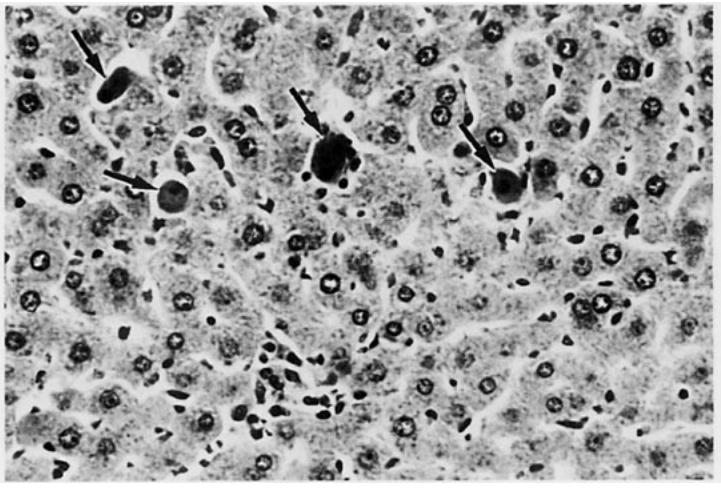

PLATE 18
Liver: Scattered necrotic hepatocytes with shrunken pyknotic nuclei and darkly stained cytoplasm (arrows). Male rat given 18,000 ppm *o*-nitroanisole at the 6-month interim evaluation of the stop-exposure feed study. H&E ×100

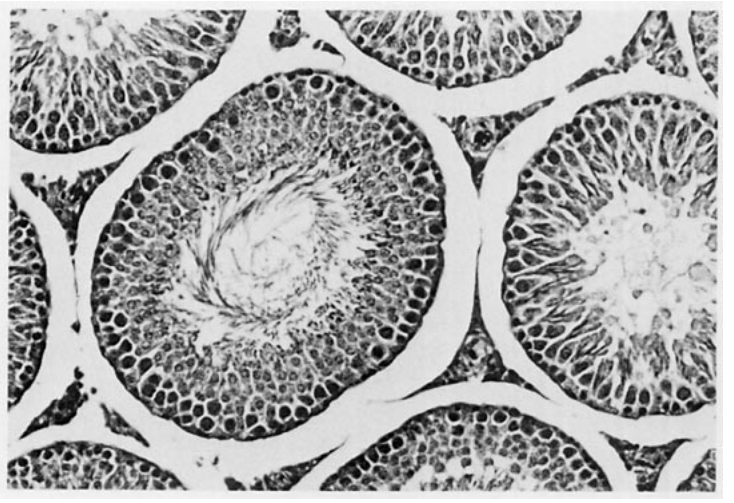

PLATE 19
Testis: For comparison with Plate 20. Control male rat in the stop-exposure feed study of *o*-nitroanisole. H&E ×50

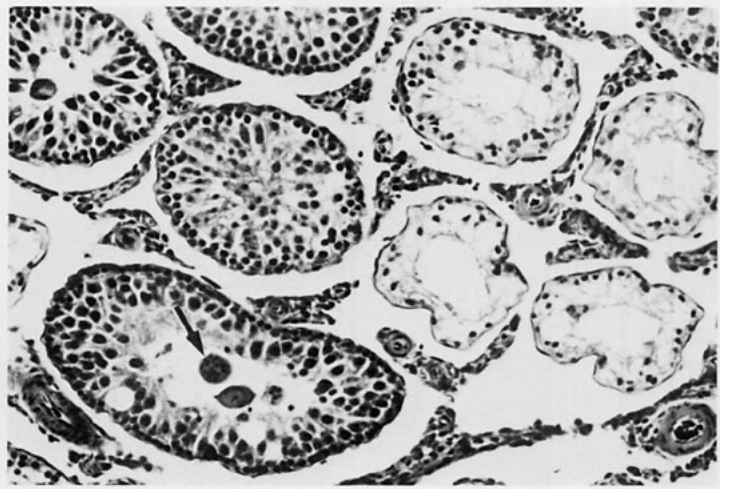

PLATE 20
Testis: Degeneration and atrophy of the seminiferous epithelium. Note the tubules containing only a few scattered sertoli cells and the degenerate multinucleate spermatids (arrows) in other tubules. Male rat given 18,000 ppm *o*-nitroanisole at the 3-month interim evaluation of the stop-exposure feed study. H&E ×50

Mice

14-Day Study

All mice survived until the end of the study (Table 21). Mean body weight gains and final mean body weights of all groups of exposed male mice were significantly lower than those of the controls. The mean body weight gain and final mean body weight of females receiving 4,000 ppm were significantly lower than those of the controls; mean body weight gains and final mean body weights of females receiving 2,000 ppm or less were similar to those of the controls. Feed consumption by males and females in the 4,000 ppm groups and females in the 2,000 ppm group was lower than that by the controls. Dietary levels of 250, 500, 1,000, 2,000, and 4,000 ppm resulted in average daily consumption levels of 25, 51, 96, 198, and 194 mg/kg for males and 36, 48, 142, 142, and 215 mg/kg for females.

At necropsy there were significant decreases in absolute brain, kidney, and liver weights of males and in absolute kidney and thymus weights of females in the 2,000 and 4,000 ppm groups (Table H8). There were significant decreases in relative kidney weights of males and the relative thymus weights of females receiving 2,000 and 4,000 ppm. In addition, there were significant increases in the relative liver weight of females and the relative heart weights of males and females receiving 4,000 ppm. These differences were primarily attributed to chemicalrelated reductions in final mean body weights; any potential direct effect of *o*-nitroanisole on these organs was masked by the more general effects associated with the lower final mean body weights. The apparent inconsistencies in absolute and relative organ weights were likely due to the disproportionate effect on adipose deposits and skeletal muscle versus the effects on glandular organs.

13-WEEK STUDY

Two males in the 200 ppm group and one male in the 600 ppm group died from wounds caused by fighting (Table 22). All other mice survived until the end of the study. The mean body weight gains and final mean body weights of male mice receiving 6,000 ppm and all exposed groups of female mice were significantly lower than those of the controls. Feed consumption by male and female mice that received 6,000 ppm was lower than that by controls, which may have been related to decreased palatability of the diet containing *o*-nitroanisole (Table 23). Dietary levels of 60, 200, 600, 2,000, and 6,000 ppm resulted in average daily consumption levels of 6, 20, 66, 180, and 540 mg/kg for males and 8, 22, 66, 200, and 540 mg/kg for females. Although male and female mice in the 6,000 ppm groups developed yellow stained fur in the perineum, there were no other clinical findings associated with chemical administration.

[a] Feed consumption is expressed as grams/animal per day.

Small but significant decreases in hemoglobin concentrations and hematocrit values were seen primarily in male and female mice receiving 2,000 and 6,000 ppm; a significant decrease in erythrocyte count was observed only in females that received 6,000 ppm (Table I6). Lower values were observed for hematocrit and hemoglobin in males from the 600 ppm group as well. The methemoglobin concentration was significantly increased only in males receiving 6,000 ppm.

The relative liver weights of females receiving 600 ppm and males and females receiving 2,000 and 6,000 ppm were significantly greater than those of the controls (Table H9). In addition, the absolute liver weights of females that received 600 ppm or more were also significantly increased, although those of males were not. These increases were attributed to the ingestion of *o*-nitroanisole. Differences in the absolute or relative weights of brain, heart, kidney, lung, spleen, testis, or thymus occurred in various exposed groups of males and females and were attributed primarily to the lower final mean body weights of the 6,000 ppm groups and were not considered biologically significant.

Liver: Hepatocyte hypertrophy associated with the ingestion of *o*-nitroanisole was seen only in male mice. The lesion was observed in mice receiving 200 ppm or more and increased in severity with increasing exposure levels (0 ppm, 0/10; 60 ppm, 0/10; 200 ppm, 3/9 (2.0); 600 ppm, 9/10 (2.8); 2,000 ppm, 10/10 (3.7); 6,000 ppm, 10/10 (3.8)). The lesion occurred primarily in the centrilobular and midzonal regions of the liver lobules. There were occasional scattered cells exhibiting cytoplasmic vacuolation or necrosis, particularly at higher exposure levels.

Dose selection rationale: Lower final mean body weights, slightly reduced feed consumption, increased liver weights, and slight differences in several hematologic parameters attributable to *o*-nitroanisole were observed in male and female mice that received 6,000 ppm. In addition, a microscopic liver lesion was observed in all male mice receiving 2,000 and 6,000 ppm and was attributed to *o*-nitroanisole administration. However, these toxic responses were rather mild and at lower exposure levels the effects became marginal to nonexistent. It was considered unlikely that the toxicity which occurred at 6,000 ppm would become life threatening, and by the end of the 13-week study, feed consumption by males receiving 6,000 ppm was increasing and approaching that by the controls. This suggested that the animals might eventually recover from their initial reaction to the 6,000 ppm concentration. Therefore, 6,000 ppm was selected as the high exposure level for the 2-year study in mice. To provide a broad range for dose response, 666 and 2,000 ppm were selected for the remaining exposure levels.

2-YEAR STUDY

Survival

Estimates of survival probabilities for male and female mice are shown in Table 24 and in the Kaplan-Meier curves in Figure 6. Survival of groups of male mice receiving 666, 2,000, and 6,000 ppm was similar to that of the controls. Although survival of females receiving 666 ppm was significantly lower than that of the controls, that of the 6,000 ppm group was slightly greater than that of controls. Thus, the ingestion of *o*-nitroanisole at dietary concentrations up to 6,000 ppm had no effect on the survival of male or female mice in the 2-year study.

Body Weights, Feed Consumption, and Clinical Findings

The ingestion of *o*-nitroanisole was associated with a dose-related reduction in mean body weight. The mean body weights of male and female mice receiving 2,000 and 6,000 ppm were lower than those of the controls throughout the study (Tables 25 and 26, and Figure 7). The mean body weights of the 6,000 ppm groups were within 20% of controls until week 17 for males and week 12 for females. Thereafter, the difference in mean body weight between the 6,000 ppm groups and the controls continued to increase. At the end of the study the final mean body weight of males receiving 6,000 ppm was 33% lower than that of the controls and the final mean body weight of females receiving 6,000 ppm was 43% lower than that of the controls. In the 2,000 ppm groups, the final mean body weight of males was 11% lower than that of controls and the final mean body weight of females was 18% lower than that of controls. The final mean body weights of male and female mice receiving 666 ppm were within 10% of the controls. Feed consumption by high-dose male and female mice was lower than that by the controls throughout the study (Tables K5 and K6). Dietary levels of 666, 2,000 and 6,000 ppm resulted in average daily consumption levels of 80, 240, and 830 mg/kg for males and 100, 320, and 1,200 mg/kg for females. Discolored urine in male and female mice was the only clinical finding attributable to *o*-nitroanisole administration.

Pathology and Statistical Analyses of Results

Summaries of the incidences of nonneoplastic lesions and neoplasms, the individual animal tumor diagnoses, the statistical analyses of primary neoplasms that occurred with an incidence of at least 5% in at least one group, and historical control incidences for the biologically significant neoplasms mentioned in this section are presented in Appendix C for male mice and Appendix D for female mice.

Liver: The absolute liver weight of males that received 2,000 ppm and the relative liver weights of all groups of exposed male mice were significantly greater than those of the controls at the 15-month interim evaluation (Table H10). The absence of a significant increase in absolute liver weight in males receiving 6,000 ppm may have been related to the significantly lower mean body weight of this group. Relative liver weights of females in the 2,000 and 6,000 ppm groups were also significantly greater than those of the controls, although the absolute liver weight of females that received 6,000 ppm was significantly lower than that of the controls. This inconsistency is also primarily due to the lower mean body weight of females receiving 6,000 ppm.

The increased liver weights at the 15-month interim evaluation were associated with generalized centrilobular cytologic alteration, which was also seen in exposed rats in the 2-year study (Tables 27, C5, and D5). The lesion was more frequent and severe in exposed males than in exposed females. The cytologic alteration consisted of enlargement of the centrilobular hepatocytes (hypertrophy), enlargement of the nuclei, and increased eosinophilic staining of the cytoplasm. Focal necrosis was seen in a number of males receiving 2,000 and 6,000 ppm at the 15-month interim evaluation, but not in females, controls, or 666 ppm males. In the 2-year study, the incidence of focal necrosis was significantly increased in all exposed male groups. The necrosis occurred primarily in the centrilobular or midzonal regions of the liver lobules and was characterized by infrequent, scattered individual cells or small foci of cells exhibiting nuclear pyknosis or karyorrhexis. These changes were often accompanied by small erythrocyte-filled spaces, diagnosed as hemorrhage, and individual Kupffer cells filled with golden brown or greenish brown pigment.

At the 15-month interim evaluation, eosinophilic foci occurred in one male and one female that received 6,000 ppm and one female that received 666 ppm (Table 27). In the 2-year study, however, the incidences of eosinophilic foci were significantly increased in all exposed male groups. In females, eosinophilic foci occurred more frequently in the 2,000 and 6,000 ppm groups, but only the incidence in the 2,000 ppm group was significantly increased.

Hepatocellular adenomas or carcinomas also occurred in a few mice at the 15-month interim evaluation (Tables 28, C1, and D1). In the 2-year study, hepatocellular adenomas were significantly increased in all exposed male groups, although the incidence of adenoma in males receiving 6,000 ppm was lower than that in males receiving 2,000 ppm (Tables 28 and C3). Hepatoblastomas, rare morphological variants of hepatocellular carcinoma, occurred in all groups of exposed male mice, but not in the controls. Thus, the incidences of hepatocellular neoplasms (hepatocellular adenoma, hepatocellular carcinoma, or hepatoblastoma) were significantly increased in the 2,000 and 6,000 ppm groups (Table C3). The incidences of hepatocellular adenoma or hepatocellular adenoma or carcinoma (combined) were significantly increased in females that received 2,000 ppm (Table D3).

Basophilic, eosinophilic, mixed cell, and clear cell foci are considered preneoplastic lesions. Foci, hepatocellular adenoma, and hepatocellular carcinoma constitute a morphological continuum. The foci were circumscribed lesions generally consisting of enlarged hepatocytes with either basophilic, eosinophilic, clear cytoplasm, or a mixture of cells with different staining properties. There was generally little or no compression of surrounding parenchyma and the hepatic cords of the lesion blended with those at the periphery. Hepatocellular adenomas were larger and usually exhibited greater distortion or alteration of hepatic architecture with loss of normal lobular structure. Hepatocellular carcinomas exhibited heterogeneous growth patterns with hepatic trabeculae four or more cell layers thick.

Hepatoblastomas were a morphological variant of hepatocellular carcinomas with typical small undifferentiated cells containing hyperchromatic nuclei and scant basophilic cytoplasm. These primitive appearing cells were usually within a larger neoplasm consisting primarily of neoplastic hepatocytes similar to those found in adenomas or carcinomas.

Nose: Several inflammatory and degenerative lesions of the nasal mucosa occurred more frequently in exposed male and female mice than in controls at the 15-month interim evaluation and in the 2-year study (Tables C5 and D5). In the 2-year study, the incidences of exudate, dilatation, and hyperplasia of the septal and Bowman's glands, hyaline degeneration of the mucosal epithelium, and respiratory metaplasia of the olfactory epithelium were significantly increased in females that received 2,000 and 6,000 ppm and, with the exception of hyaline degeneration, in males that received 6,000 ppm (Table 29). The inflammatory exudate consisted of mucus, degenerating neutrophils, and cellular debris on the mucosal surface or within the lumens of the septal glands and Bowman's glands. The lumens of the glands were often dilated and the glandular epithelial cells were enlarged and prominent. The hyaline degeneration was characterized by the accumulation of large hyaline droplets in secretory cells of the respiratory epithelium and olfactory epithelium, particularly near the junction of these two epithelial types. The respiratory metaplasia of the olfactory epithelium was multifocal in distribution and often located on the dorsal wall of the dorsal meatus and posterior medial aspects of the nasoturbinates. In the affected areas the specialized olfactory epithelium was replaced by ciliated columnar epithelium.

Lung: Focal proliferation of the bronchiolar epithelium was observed in exposed mice, particularly males, but not in controls (males: 0 ppm, 0/50; 666 ppm, 2/50; 2,000 ppm, 13/50; 6,000 ppm, 14/50; females: 0/50; 3/50; 5/50; 4/50; Tables C5 and D5). The lesion was characterized by subtle extension of the cuboidal bronchiolar epithelium into the adjacent alveoli. Usually only one or a few bronchioles in the lung sections were affected.

Kidney: The relative kidney weights of all exposed males and of females receiving 6,000 ppm were significantly greater than those of the controls at the 15-month interim evaluation (Table H10). Although absolute kidney weights of males receiving 666 and 2,000 ppm were slightly greater than the controls, that of males receiving 6,000 ppm was significantly lower than that of controls. The increases in relative kidney weights of the 666 and 2,000 ppm males suggest a direct chemical-related effect, but the

kidney weight differences in the 6,000 ppm groups are largely attributable to the significantly lower mean body weights.

There were no differences in the incidences of kidney lesions between control and female mice receiving 6,000 ppm at the 15-month interim evaluation (Tables C5 and D5). In male mice, however, renal tubule regeneration occurred less frequently in the 6,000 ppm group than in the controls. In the 2-year study, the incidences of renal tubule regeneration in females that received 2,000 ppm and males and females that received 6,000 ppm were significantly decreased (Table 30). Moreover, the average severity of the lesion was also lower in males receiving 6,000 ppm than in controls, but not substantially lower in exposed females. Focal renal tubule regeneration is the most overt histologic manifestation of chronic renal disease in aging mice and consists of focal collections of tubules with epithelium having basophilic cytoplasm and enlarged vesicular nuclei. The incidence of lymphoid hyperplasia in males and females that received 6,000 ppm was also significantly decreased. There was also a significantly decreased incidence of focal mineralization in females receiving 6,000 ppm.

Pituitary gland: An adenoma of the pars distalis was seen in one control female and a carcinoma was seen in one female that received 2,000 ppm at the 15-month interim evaluation (Table D1). In the 2-year study, however, there was a significantly decreased incidence of pars distalis adenomas in females receiving 6,000 ppm and a corresponding decreased incidence of focal hyperplasia (adenoma: 7/49, 6/47, 8/48, 0/48; hyperplasia: 9/49, 10/47, 5/48, 0/48; Tables D1 and D5). These lesions may be related to nutritional or physiological changes associated with the lower mean body weights of female mice in the 6,000 ppm group, rather than to a direct chemical-related effect on the pituitary gland.

[c] Average severity grade of lesions in affected animals: 1 = minimal, 2 = mild, 3 = moderate, 4 = marked

Harderian gland: The harderian glands, specialized lacrimal glands located posterior to the eyes, were examined microscopically only when they were observed to be enlarged at necropsy. The incidences of harderian gland adenoma or carcinoma (combined) in males that received 2,000 and 6,000 ppm were significantly decreased (10/50, 4/50, 2/50, 3/50; Table C3). However, the incidence in the concurrent controls is substantially higher than that in the NTP historical controls and is the highest observed in an individual control group (48/872 (6%), range 0%-20%; Table C4b). Thus, the decreased incidences in the exposed groups may not be chemical related.

Adrenal gland: Adrenal cortical adenomas in males occurred in the control, 666, and 2,000 ppm groups, but not in the 6,000 ppm group. Although the incidence of adenomas in the 6,000 ppm group was significantly decreased (Table C3), the incidence in control males is substantially higher than that in NTP historical controls and is the highest observed in an individual control group (14/851 (2%), range 0%-14%; Table C4c). As with the harderian gland neoplasms, the decreased incidence in males receiving 6,000 ppm is not considered chemical related.

Genetic Toxicology

o-Nitroanisole was tested in two laboratories using a preincubation protocol for induction of gene mutations in five strains of *Salmonella typhimurium* in the presence and the absence of Aroclor 1254-induced male Sprague-Dawley rat or Syrian hamster liver S9 (Table G1). In the first study (Haworth *et al.*, 1983), concentrations of 33 to 2,150 μg/plate were tested in strains TA98, TA100, TA1535, and TA1537; positive responses were observed only in strain TA100, with and without S9. In the second study, strains TA97, TA98, TA100, and TA1535 were tested with concentrations up to 3,333 μg/plate; positive responses were again noted for TA100, with and without S9, and also for TA1535, without S9. Both of these strains have the same DNA target site, and are reverted via base substitution. In cytogenetic tests with Chinese hamster ovary cells, *o*-nitroanisole induced sister chromatid exchanges with and without Aroclor 1254-induced male Sprague-Dawley rat liver S9 (Table G2; Galloway *et al.*, 1987); at higher doses (above 123 μg/mL without S9, and above 811 μg/mL with S9), delayed harvest times were used to offset *o*-nitroanisole-induced cell cycle delay and allow for accumulation of sufficient metaphase cells for analysis. In the Chinese hamster ovary cell chromosomal aberrations test (Table G3; Galloway *et al.*, 1987), *o*-nitroanisole induced a significant increase in aberrations at the highest dose (1,060 μg/mL) tested in the presence of S9 activation; this response was due mainly to an increase in breaks which occurred in the long arm of the X chromosome. No increase in aberrations was observed in either of the two trials conducted without S9. *o*-Nitroanisole was positive in the mouse lymphoma L5178Y cell assay for induction of trifluorothymidine resistance in the absence of S9 activation; it was not tested with S9 (Table G4). The first of three trials was considered inconclusive because although a negative response was obtained at the highest nonlethal dose tested, the relative total growth of the treated cultures was not markedly decreased. In the remaining two trials, a dose-related increase in trifluorothymidine-resistant colonies was observed and significantly increased responses occurred at doses where the relative total growth was depressed below 50%.

DISCUSSION AND CONCLUSIONS

o-Nitroanisole is used primarily as a precursor in the synthesis of *o*-anisidine, an intermediate in the manufacture of many azo dyes. *o*-Nitroanisole is one of a series of single ring aromatic amines which have been evaluated for carcinogenic potential by the NTP. This class of chemicals was selected for evaluation because of occupational and consumer exposure and because several aromatic amines have been identified as human bladder carcinogens. Most of these single ring compounds have been used or are still used in the manufacture of dyes.

During 14-day and 13-week studies administration of *o*-nitroanisole caused an anemia in both rats and mice which was characterized by increased levels of methemoglobin and accelerated destruction of erythrocytes. In the 13-week rat study, reduced mean body weights and decreased feed consumption were observed in groups receiving the two highest dietary concentrations. In addition, absolute and relative liver, kidney, and spleen weights were increased in exposed male and female rats, and absolute and relative thymus weights were decreased in exposed females and increased in exposed males. In rats, lesions associated with *o*-nitroanisole exposure were present in the spleen, liver, and kidney, but the most severely affected organ was the urinary bladder. Diffuse hyperplasia of the transitional epithelium of the urinary bladder occurred in all rats that received 6,000 and 18,000 ppm in the 13-week study. Focal squamous metaplasia of the urinary bladder occurred in all females and two males receiving 18,000 ppm. Transitional cell neoplasms were present in three males and four females that received 18,000 ppm. The Pathology Working Group that reviewed the 13-week study questioned whether or not the lesions would persist or regress if chemical exposure was discontinued. Therefore, to investigate the biological potential of these lesions, a stop-exposure study with interim evaluations at 3, 6, 9, and 15 months was added to the design of the 2-year rat study. The only chemical-related lesion present in mice during the 13-week study was hepatocellular hypertrophy which occurred only in male mice and increased in severity with exposure levels above 200 ppm.

During the 2-year studies survival of male rats that received 2,000 ppm was lower than that of the controls, primarily as a result of an increased severity of nephropathy. However, the survival of female rats receiving 2,000 ppm or less, male rats receiving 222 and 666 ppm, all exposed male mice, and female mice receiving 2,000 and 6,000 ppm was similar to that of the controls. Survival of male and female rats that received 6,000 and 18,000 ppm in the stop-exposure study was markedly reduced as a result of moribund deaths associated with the presence of urinary bladder neoplasms. The mean body weights of the stop-exposure groups were also much lower than those of the controls.

The dose-response trend for increased incidences of urinary bladder neoplasms in rats is illustrated in Table 31. Continuous administration of 222 or 666 ppm *o*-nitroanisole had no effect on the bladder over the 2-year duration of the study. Exposure to 2,000 ppm for 2 years caused marginal increased incidences of transitional cell neoplasms in female rats and slightly increased incidences of nonneoplastic proliferative lesions of the bladder in both males and females. Exposure to 6,000 ppm for 3 months increased the incidence of transitional cell hyperplasia in female rats, and after 3 months of exposure to 18,000 ppm, the incidence of hyperplasia of the transitional epithelium was increased in both sexes and a transitional cell carcinoma was observed in a male rat. These results were similar to the observations in the 13-week study. After 6 months of exposure to 6,000 ppm, transitional cell hyperplasia was observed in all male and female rats examined; transitional cell papillomas were present in two male rats, while 6 months of exposure to 18,000 ppm resulted in transitional cell carcinomas in all male and female rats examined. Therefore, increasing the dietary exposure level from 2,000 to 6,000 ppm was associated with an increase in the incidence of neoplasms and markedly reduced latency for development of both carcinomas and preneoplastic lesions.

A similar type of dose response for the induction of urinary bladder neoplasms has been observed in

TABLE 31
Response of the Male Rat Urinary Bladder to *o*-Nitroanisole

Dose (ppm)	Exposure Time (weeks)	Study Length (weeks)	Transitional Hyperplasia	Transitional Papilloma	Transitional Carcinoma
222	103	103	0	0	0
666	103	103	0	0	0
2,000	103	103	0	2/50	0
6,000	13	13	0	0	0
6,000	26	28	10/10	2/10	0
6,000	26	40	10/10	2/10	3/10
18,000	13	13	9/10	0	1/10
18,000	26	28	0	0	10/10

F344/N rats exposed to *N*-butyl-*N*-(4-hydroxybutyl)-nitrosamine (BBN) (Ito *et al.*, 1984), or to the well-studied bladder carcinogen *N*-[4-(5-nitro-2-furyl)-2-thiazolyl]formamide (FANFT) (Arai *et al.*, 1983; Hasegawa *et al.*, 1986). For both compounds, the incidence of bladder neoplasms increases and the latency decreases as exposure concentration increases, so at higher dose levels neoplasms may be induced after a shorter period of chemical exposure.

From an analysis of the FANFT data in the context of a biologically based two-event model of carcinogenesis, Greenfield *et al.* (1984) have proposed that this type of response can be expected for a chemical which affects neoplasm formation both by its ability to produce lesions in the DNA of a target cell population and its ability to stimulate increased proliferation of the target cell population. For the present discussion the target cell population is the transitional epithelium of the urinary bladder and its precursor or stem cells. For the FANFT data the model assumes that at low doses the neoplasm incidence will increase primarily as a result of the genotoxic effects of the chemical; at these dose levels cell proliferative effects are minimal. As the dose increases, potentially preneoplastic genetic damage also increases; however, because of cytotoxicity, regenerative proliferation of the transitional epithelium of the urinary bladder also occurs. The superposition of increased genetic damage and increased cell proliferation results in an increase in neoplasm incidence substantially greater than would occur from either one alone. Over the range of dose concentrations at which cell proliferation increases, the slope of the dose response curve increases sharply and the latency for neoplasm development decreases.

Qualitatively there appears to be reasonable agreement between the predictions of the model and the current results for *o*-nitroanisole. After 3 months of exposure to 18,000 ppm, hyperplasia had increased the thickness of the transitional epithelium to at least 30 cell layers, compared to a 3- to 10-cell layer thickness for the transitional epithelium of controls. In addition, absolute and relative urinary bladder weights of the 18,000 ppm groups were significantly increased at the 3-, 6-, and 9-month interim evaluations. Exposure to 2,000 ppm for 13 weeks had no effect on the bladder; exposure to 2,000 ppm for 2 years caused focal hyperplasia in six females and two males, a transitional cell papilloma in one female, and a carcinoma in another. Therefore, between 2,000 and 6,000 ppm there was a marked increase in both cell proliferation and neoplasm incidence and a marked reduction in neoplasm latency.

Numerous factors may be involved with increasing the rate of cell proliferation in the urinary bladder, and these have been discussed in recent publications (Cohen *et al.*, 1991; Okamura *et al.*, 1991). For most chemicals the underlying cause of increased proliferation has not been specifically identified, although it is often attributed to regenerative hyperplasia associated with some type of chemical-related cytotoxicity or irritant response. The character of the toxicity responsible for inducing hyperplasia in the bladder of rats that received 6,000 or 18,000 ppm is uncertain.

The major route of metabolism of *o*-nitroanisole is oxidative demethylation to *o*-nitrophenol, which appears in the urine predominantly as the sulfate conjugate. A second pathway involves nitroreduction to *o*-anisidine; at blood concentrations at which the metabolism and elimination of *o*-nitroanisole is linear, *o*-anisidine is a minor metabolite formed in the liver. However, at higher doses the *o*-nitrophenyl sulfate pathway may saturate, leading to the formation of proportionately more *o*-anisidine. The metabolism of *o*-anisidine has not been determined. However, it is also likely to be oxidatively demethylated to *o*-aminophenol, which in turn would normally be sulfated or glucuronidated. However, in the presence of saturating levels of *o*-nitroanisole, the additional *o*-aminophenol formed would probably appear unconjugated in the urine. In theory *o*-aminophenol could be reabsorbed by the urinary bladder epithelium and oxidized to the reactive and cytotoxic *o*-quinoneimine. However, the necrosis and cell death that often accompany intracellular formation or reaction of reactive intermediates was not observed in the bladders of rats exposed to *o*-nitroanisole.

Figure 8 lists the compounds which have caused urinary bladder neoplasms in rats in previous NTP 2-year feed studies, and it is apparent that several of these compounds bear a close structural resemblance to *o*-nitroanisole. Moreover, most are genotoxic and induce bladder neoplasms over the same range of exposures as *o*-nitroanisole, suggesting that a common mechanism may be involved. The most potent rat bladder carcinogen to be evaluated by the NTP is *o*-anisidine, and therefore it is tempting to try to relate some common structural feature or metabolite of the other compounds to *o*-anisidine (NCI, 1978b). The major route of metabolism of *o*-toluidine is 4-hydroxylation to 3-methyl-4-aminophenol (4-hydroxy-*o*-toluidine) followed by conjugation (NCI, 1979a). It is also likely that *p*-cresidine is oxidatively demethylated to *o*-amino-4-methylphenol and conjugated (NCI, 1979b). The major route of metabolism of 4-amino-2-nitrophenol is probably direct conjugation, with nitro-reduction to 2,4-diaminophenol in the liver being a minor route (NCI, 1978a).

Exposure to *o*-nitroanisole caused a marginal increased incidence of renal tubule neoplasms in rats in the 2-year feed study. Renal tubule adenomas were present in one male in each of the 222, 666, and 2,000 ppm groups, and renal tubule carcinomas were present in two additional males that received 2,000 ppm. The increased incidence in the 2,000 ppm group was statistically significant and the incidence and the severity of nephropathy were increased in exposed animals. However, very few preneoplastic proliferative lesions were present; focal hyperplasia of the renal tubule epithelium was present in three 222 ppm males and two 2,000 ppm males. Among rats in the stop-exposure study, hyperplasia of the transitional epithelium lining the renal pelvis was first observed at the 6-month interim evaluation but was present in rats from both the 6,000 and 18,000 ppm groups throughout the duration of the study. At the end of the stop-exposure study, transitional cell papillomas were present in three males and one female and transitional cell carcinomas were present in six males and one female that received 18,000 ppm. Because of early mortality in the 6,000 and 18,000 ppm groups due to the presence of urinary bladder neoplasms, it is likely that these incidences are an underestimate of the carcinogenic potential of *o*-nitroanisole in the kidney.

Consumption of diets containing *o*-nitroanisole for 2 years caused a dose-related increased incidence of focal hyperplasia of the forestomach mucosa as well as a slight dose-related increased incidence of forestomach ulcers in male and female rats. In addition, squamous cell papillomas or carcinomas were present in one female receiving 222 ppm, two males receiving 666 ppm, and two males and two females receiving 2,000 ppm. Among groups of rats from the

FIGURE 8
Compounds Causing Bladder Neoplasms in Rats

stop-exposure study, adenomatous polyps of the large intestine were observed at all interim evaluations. At the end of the stop-exposure study, the incidence of adenomatous polyps was increased in the exposed groups, and the incidence of carcinomas of the large intestine was significantly increased in both the 6,000 and 18,000 ppm groups. Spontaneous neoplasms of the forestomach and large intestine are uncommon in F344/N rats and the increased incidences observed in the present study are considered to be related to chemical exposure.

The incidence of mononuclear cell leukemia was increased and exceeded the historical control rate in male rats that received 666 and 2,000 ppm and female rats that received 2,000 ppm of *o*-nitroanisole for 2 years. The incidence of mononuclear cell leukemia in control rats from the stop-exposure study was approximately the same as that for controls in the 2-year study; however, the incidence of mononuclear cell leukemia in exposed rats of the stop-exposure study was very low, most likely as a result of the markedly reduced survival in these groups.

Exposure to *o*-nitroanisole was associated with increased absolute and relative liver weights and increased incidences of liver lesions in both rats and mice. The increased absolute and relative liver weights were consistent with the liver being the primary organ involved with metabolism of *o*-nitroanisole. In rats the lesions were primarily nonneoplastic and although a few hepatocellular neoplasms were present in exposed rats, the incidences were low and not dose related. The incidences of focal necrosis and preneoplastic foci of cellular alteration were increased in exposed male mice. In addition, the incidences of hepatocellular adenoma and hepatocellular carcinoma or hepatoblastoma (combined) were significantly increased in male mice receiving 2,000 and 6,000 ppm; the incidence of hepatocellular adenoma or carcinoma (combined) was significantly increased in all exposed groups of male mice. The strong dose-related increased incidence of neoplasms in male mice was considered clear evidence of carcinogenic activity. In female mice the incidence of hepatocellular adenoma was significantly increased in the 2,000 ppm group but was not significantly increased in the 666 or 6,000 ppm groups. However, the significant depression in mean body weight (54% of control from week 53 to week 101) in 6,000 ppm female mice undoubtedly influenced the incidence of hepatocellular neoplasms in this group.

As a group, the other structurally similar chemicals which caused urinary bladder neoplasms in rats did not produce uniform results in mice. *o*-Anisidine and *p*-cresidine produced bladder neoplasms in male and female mice, and *p*-cresidine produced liver neoplasms in female mice (NCI, 1978b; 1979b). *o*-Toluidine caused hemangiosarcomas in male mice and liver neoplasms in female mice (NCI, 1979a), while C.I. Disperse Blue 1 produced an equivocal response in the liver of male mice and no evidence in female mice (NTP, 1986), and 4-amino-2-nitrophenol was negative in male and female mice (NCI, 1978a). Therefore, the response in mice was different for each chemical and each sex, and in general, mice were less responsive than rats.

The effectiveness of four of the most commonly used *in vitro* short-term genetic toxicity tests for prediction of chemical carcinogenicity was evaluated using 114 chemicals tested by the NTP. The tests used were induction of gene mutations in *Salmonella typhimurium* (SAL) and mouse lymphoma L5178Y cells (MLA), and induction of sister chromatid exchanges (SCE) and chromosome aberrations (Abs) in Chinese hamster ovary (CHO) cells (Tennant *et al.*, 1987; Zeiger *et al.*, 1990). The (SAL) assay was shown to have the lowest sensitivity, the highest specificity, and the highest positive predictivity for carcinogenicity of the four *in vitro* tests. The other tests had lower predictivities for carcinogenicity, and no combination of the four tests was more predictive for carcinogenicity than *S. typhimurium* alone.

The aromatic nitro group of *o*-nitroanisole is a molecular feature which provides an alert to potential DNA reactivity (Ashby and Tennant, 1991). *o*-Nitroanisole gave positive results in all four (SAL, MLA, SCE, Abs) of the NTP *in vitro* genetic toxicity tests, and one of the metabolites of *o*-nitroanisole (*o*-anisidine) was also mutagenic in these same four assays. Chemicals that are mutagenic in *S. typhimurium* and contain a structural alert are more likely to induce neoplasms in both rats and mice than chemicals that do not have these characteristics. These positive results in genotoxicity assays, and the structurally alerting nitro group, were predictive of the results of the bioassay, where

evidence of carcinogenicity was observed in both rats and mice (Tennant *et al.*, 1990).

CONCLUSIONS

Under the conditions of these feed studies there was *clear evidence of carcinogenic activity** of *o*-nitroanisole in male and female F344 rats that received diets containing 6,000 or 18,000 ppm for 6 months based on overall increased incidences of benign and malignant neoplasms of the urinary bladder, transitional cell neoplasms of the kidney, and benign and malignant neoplasms of the large intestine. There was a chemical-related increased incidence of mononuclear cell leukemia in male and female rats receiving diets containing 222, 666, or 2,000 ppm *o*-nitroanisole for 2 years. Marginally increased incidences of uncommon renal tubule neoplasms in male rats and forestomach neoplasms in male and female rats were considered uncertain findings. There was *clear evidence of carcinogenic activity* of *o*-nitroanisole in male $B6C3F_1$ mice based on increased incidences of benign and malignant hepatocellular neoplasms. There was *some evidence of carcinogenic activity* of *o*-nitroanisole in female $B6C3F_1$ mice based on increased incidences of hepatocellular adenomas.

Increased severity of nephropathy in male rats, and increased incidences of focal hyperplasia of the renal tubule epithelium and forestomach ulcers in male rats, and of transitional cell hyperplasia of the urinary bladder, focal hyperplasia of the forestomach, and hyperplasia of transitional epithelium of the kidney pelvis in male and female rats were associated with exposure to *o*-nitroanisole.

* Explanation of Levels of Evidence of Carcinogenic Activity is on page 12. A summary of the Technical Reports Review Subcommittee comments and the public discussion on this Technical Report appear on page 14.

Zeiger, E. Anderson, B., Haworth, S., Lawlor, T., and Mortelmans, K. (1992). *Salmonella* mutagenicity tests. V. Results from the testing of 311 chemicals. *Environ. Mol. Mutagen.* **19** (Suppl. 21), 2-141.

APPENDIX A
SUMMARY OF LESIONS IN MALE RATS IN THE 2-YEAR FEED STUDY OF *o*-NITROANISOLE

TABLE A1
Summary of the Incidence of Neoplasms in Male Rats in the 2-Year Feed Study of *o*-Nitroanisole[a]

	0 ppm	222 ppm	666 ppm	2,000 ppm
Disposition Summary				
Animals initially in study	60	60	60	60
15-Month interim evaluation	10	10	10	10[b]
Early deaths				
Moribund	16	13	24	35
Natural deaths	2	3	2	6
Survivors				
Died last week of study				1
Terminal sacrifice	32	34	24	8
Animals examined microscopically	60	60	60	59
15-Month Interim Evaluation				
Alimentary System				
Liver	(10)	(10)	(10)	(9)
Mesentery	(2)	(2)	(2)	
Cardiovascular System				
None				
Endocrine System				
Adrenal gland, medulla	(10)			(9)
Ganglioneuroma	1 (10%)			
Pituitary gland	(10)	(1)		
Pars distalis, adenoma	3 (30%)	1 (100%)		
General Body System				
None				
Genital System				
Epididymis	(10)	(10)	(10)	(9)
Preputial gland	(10)	(10)	(9)	(9)
Carcinoma		1 (10%)	1 (11%)	1 (11%)
Testes	(10)	(10)	(10)	(9)
Bilateral, interstitial cell, adenoma	4 (40%)	1 (10%)	4 (40%)	4 (44%)
Interstitial cell, adenoma	1 (10%)	5 (50%)	5 (50%)	3 (33%)
Hematopoietic System				
Bone marrow	(10)			(9)
Spleen	(10)	(10)	(10)	(9)

TABLE A1
Summary of the Incidence of Neoplasms in Male Rats in the 2-Year Feed Study of *o*-Nitroanisole (continued)

	0 ppm	222 ppm	666 ppm	2,000 ppm
15-Month Interim Evaluation (continued)				
Integumentary System				
Skin	(10)	(1)		(9)
Subcutaneous tissue, scrotum, fibrosarcoma		1 (100%)		
Musculoskeletal System				
Skeletal muscle	(1)			
Nervous System				
Brain	(10)			(9)
Glioma malignant	1 (10%)			
Respiratory System				
Lung	(10)	(1)		(9)
Alveolar/bronchiolar adenoma, multiple	1 (10%)	1 (100%)		
Special Senses System				
None				
Urinary System				
None				
Systemic Lesions				
Multiple organs[c]	(10)	(10)	(10)	(9)
Leukemia mononuclear		1 (10%)		2 (22%)
Mesothelioma malignant	1 (10%)			
Neoplasm Summary				
Total animals with primary neoplasms[d]	8	7	9	8
Total primary neoplasms	12	11	10	10
Total animals with benign neoplasms	8	6	9	7
Total benign neoplasms	10	8	9	7
Total animals with malignant neoplasms	2	2	1	3
Total malignant neoplasms	2	3	1	3

TABLE A1

	0 ppm	222 ppm	666 ppm	2,000 ppm
2-Year Study				
Alimentary System				
Intestine large, cecum	(48)	(48)	(49)	(47)
Intestine large, colon	(48)	(48)	(50)	(48)
Intestine large, rectum	(46)	(49)	(50)	(49)
Intestine small, duodenum	(49)	(47)	(50)	(47)
Intestine small, ileum	(48)	(47)	(48)	(46)
Intestine small, jejunum	(48)	(47)	(48)	(48)
Adenocarcinoma				1 (2%)
Liver	(50)	(50)	(50)	(50)
Hepatocellular carcinoma		1 (2%)		
Hepatocellular adenoma		3 (6%)	1 (2%)	1 (2%)
Hepatocellular adenoma, multiple				1 (2%)
Mesentery	(10)	(11)	(5)	(9)
Histiocytic sarcoma	1 (10%)			
Pancreas	(49)	(49)	(50)	(48)
Carcinoma, metastatic				1 (2%)
Histiocytic sarcoma	1 (2%)			
Acinar cell, adenoma	5 (10%)	3 (6%)		5 (10%)
Pharynx		(1)		
Palate, squamous cell papilloma		1 (100%)		
Stomach, forestomach	(50)	(50)	(50)	(50)
Squamous cell carcinoma			1 (2%)	1 (2%)
Squamous cell papilloma			1 (2%)	1 (2%)
Stomach, glandular	(50)	(49)	(50)	(50)
Cardiovascular System				
Heart	(50)	(50)	(50)	(50)
Schwannoma benign			1 (2%)	
Endocrine System				
Adrenal gland, cortex	(48)	(50)	(50)	(49)
Adenoma	2 (4%)		1 (2%)	
Adrenal gland, medulla	(49)	(50)	(50)	(49)
Pheochromocytoma malignant	4 (8%)	3 (6%)	2 (4%)	
Pheochromocytoma benign	7 (14%)	5 (10%)	8 (16%)	9 (18%)
Bilateral, pheochromocytoma malignant	2 (4%)			
Bilateral, pheochromocytoma benign		2 (4%)		1 (2%)
Islets, pancreatic	(49)	(49)	(50)	(48)
Adenoma	1 (2%)	3 (6%)	4 (8%)	2 (4%)
Adenoma, multiple		1 (2%)		
Mixed tumor benign			2 (4%)	1 (2%)
Parathyroid gland	(47)	(46)	(47)	(48)
Adenoma			1 (2%)	1 (2%)
Pituitary gland	(50)	(50)	(49)	(49)
Pars distalis, adenoma	14 (28%)	11 (22%)	9 (18%)	4 (8%)
Pars distalis, carcinoma	1 (2%)		1 (2%)

	0 ppm	222 ppm	666 ppm	2,000 ppm
2-Year Study (continued)				
Special Senses System				
Ear			(1)	
Pinna, schwannoma malignant			1 (100%)	
Eye	(1)	(1)	(2)	(2)
Harderian gland				(2)
Carcinoma				1 (50%)
Zymbal's gland		(1)		(1)
Carcinoma		1 (100%)		1 (100%)
Urinary System				
Kidney	(49)	(50)	(50)	(49)
Renal tubule, adenoma		1 (2%)	1 (2%)	1 (2%)
Renal tubule, carcinoma				2 (4%)
Urinary bladder	(50)	(50)	(50)	(50)
Transitional epithelium, carcinoma				1 (2%)
Systemic Lesions[a]				
Multiple organs	(50)	(50)	(50)	(50)
Histiocytic sarcoma	1 (2%)			
Leukemia mononuclear	26 (52%)	25 (50%)	42 (84%)	34 (68%)
Mesothelioma malignant	1 (2%)		1 (2%)	3 (6%)
Neoplasm Summary				
Total animals with primary neoplasms	50	49	50	50
Total primary neoplasms	147	133	140	137
Total animals with benign neoplasms	50	48	47	48
Total benign neoplasms	96	90	85	78
Total animals with malignant neoplasms	35	33	45	44
Total malignant neoplasms	51	43	55	59
Total animals with metastatic neoplasms	1		1	2
Total metastatic neoplasms	1		1	2

[a] Number of animals examined microscopically at site and number of animals with lesion.
[b] Includes one animal killed moribund before the interim evaluation.
[c] Number of animals with any tissue examined microscopically
[d] Primary neoplasms: all neoplasms except metastatic neoplasms

(T)Terminal sacrifice

[a] Number of neoplasm-bearing animals/number of animals examined. Denominator is number of animals examined microscopically for adrenal gland, bone marrow, brain, clitoral gland, epididymis, gallbladder (mouse), heart, kidney, larynx, liver, lung, nose, ovary, pancreas, parathyroid gland, pituitary gland, preputial gland, prostate gland, salivary gland, spleen, testes, thyroid gland, and urinary bladder; for other tissues, denominator is number of animals necropsied.

[b] Kaplan-Meier estimated neoplasm incidence at the end of the study after adjustment for intercurrent mortality

[c] Observed incidence at terminal kill

[d] Beneath the control incidence are the P values associated with the trend test. Beneath the dosed group incidence are the P values corresponding to pairwise comparisons between the controls and that dosed group. The life table analysis regards neoplasms in animals dying prior to terminal kill as being (directly or indirectly) the cause of death. The logistic regression tests regard these lesions as nonfatal. The Cochran-Armitage and Fisher exact tests compare directly the overall incidence rates. For all tests, a negative trend or a lower incidence in a dose group is indicated by N.

[e] Not applicable; no neoplasms in animal group

[f] Value of statistic cannot be computed

Fisher exact test		P=0.643N	P=0.643N	P=0.643N

(T)Terminal sacrifice
[a] Number of neoplasm-bearing animals/number of animals examined. Denominator is number of animals examined microscopically for adrenal gland, bone marrow, brain, clitoral gland, epididymis, gallbladder (mouse), heart, kidney, larynx, liver, lung, nose, ovary, pancreas, parathyroid gland, pituitary gland, preputial gland, prostate gland, salivary gland, spleen, testes, thyroid gland, and urinary bladder; for other tissues, denominator is number of animals necropsied.
[b] Kaplan-Meier estimated neoplasm incidence at the end of the study after adjustment for intercurrent mortality
[c] Observed incidence at terminal kill
[d] Beneath the control incidence are the P values associated with the trend test. Beneath the dosed group incidence are the P values corresponding to pairwise comparisons between the controls and that dosed group. The life table analysis regards neoplasms in animals dying prior to terminal kill as being (directly or indirectly) the cause of death. The logistic regression tests regard these lesions as nonfatal. The Cochran-Armitage and Fisher exact tests compare directly the overall incidence rates. For all tests, a negative trend or a lower incidence in a dose group is indicated by N.
[e] Not applicable; no neoplasms in animal group

TABLE C1
Summary of the Incidence of Neoplasms in Male Mice in the 2-Year Feed Study of o-Nitroanisole (continued)

	0 ppm	666 ppm	2,000 ppm	6,000 ppm
2-Year Study (continued)				
Hematopoietic System				
Bone marrow	(50)	(50)	(50)	(50)
Hemangiosarcoma	2 (4%)			
Lymph node	(50)	(50)	(50)	(50)
Lymph node, mandibular	(48)	(49)	(49)	(49)
Lymph node, mesenteric	(47)	(49)	(46)	(50)
Histiocytic sarcoma				1 (2%)
Spleen	(50)	(50)	(49)	(48)
Hemangiosarcoma	1 (2%)			
Thymus	(47)	(47)	(45)	(48)
Histiocytic sarcoma			1 (2%)	
Integumentary System				
Skin	(50)	(50)	(50)	(50)
Squamous cell papilloma	1 (2%)			
Subcutaneous tissue, hemangioma		1 (2%)		
Subcutaneous tissue, hemangiosarcoma	1 (2%)			1 (2%)
Musculoskeletal System				
Skeletal muscle	(1)		(1)	
Hepatoblastoma, metastatic, liver			1 (100%)	
Nervous System				
None				
Respiratory System				
Lung	(50)	(50)	(50)	(50)
Alveolar/bronchiolar adenoma	5 (10%)	9 (18%)	2 (4%)	3 (6%)
Alveolar/bronchiolar adenoma, two, multiple		1 (2%)	1 (2%)	
Alveolar/bronchiolar adenoma, three, multiple			1 (2%)	
Alveolar/bronchiolar carcinoma	1 (2%)	2 (4%)		1 (2%)
Pheochromocytoma malignant, metastatic, adrenal gland				1 (2%)
Hepatoblastoma, metastatic, liver			1 (2%)	
Hepatocellular carcinoma, metastatic, liver	3 (6%)			
Histiocytic sarcoma			1 (2%)	
Special Senses System				
Harderian gland	(10)	(4)	(2)	(3)
Adenoma	8 (80%)	4 (100%)	2 (100%)	3 (100%)
Adenoma, two, multiple	1 (10%)			
Carcinoma	1 (10%)			

TABLE C1
Summary of the Incidence of Neoplasms in Male Mice in the 2-Year Feed Study of *o*-Nitroanisole (continued)

	0 ppm	666 ppm	2,000 ppm	6,000 ppm
2-Year Study (continued)				
Urinary System				
Kidney	(50)	(50)	(50)	(50)
Renal tubule, adenoma	1 (2%)		1 (2%)	
Urinary bladder	(50)	(50)	(49)	(50)
Transitional epithelium, papilloma	1 (2%)			
Systemic Lesions				
Multiple organs	(50)	(50)	(50)	(50)
Histiocytic sarcoma			1 (2%)	1 (2%)
Lymphoma malignant lymphocytic	1 (2%)			1 (2%)
Lymphoma malignant mixed	2 (4%)	6 (12%)	3 (6%)	2 (4%)
Lymphoma malignant undifferentiated cell	1 (2%)	1 (2%)	1 (2%)	5 (10%)
Neoplasm Summary				
Total animals with primary neoplasms	38	41	49	41
Total primary neoplasms	66	81	88	67
Total animals with benign neoplasms	29	37	45	31
Total benign neoplasms	47	52	53	37
Total animals with malignant neoplasms	16	23	27	26
Total malignant neoplasms	19	29	35	30
Total animals with metastatic neoplasms	3		2	1
Total metastatic neoplasms	3		4	1

[a] Number of animals examined microscopically at site and number of animals with lesion.
[b] Number of animals with any tissue examined microscopically
[c] Primary neoplasms: all neoplasms except metastatic neoplasms

TABLE C3
Statistical Analysis of Primary Neoplasms in Male Mice in the 2-Year Feed Study of *o*-Nitroanisole (continued)

(T)Terminal sacrifice
[a] Number of neoplasm-bearing animals/number of animals examined. Denominator is number of animals examined microscopically for adrenal gland, bone marrow, brain, clitoral gland, epididymis, gallbladder (mouse), heart, kidney, larynx, liver, lung, nose, ovary, pancreas, parathyroid gland, pituitary gland, preputial gland, prostate gland, salivary gland, spleen, testes, thyroid gland, and urinary bladder; for other tissues, denominator is number of animals necropsied.
[b] Kaplan-Meier estimated neoplasm incidence at the end of the study after adjustment for intercurrent mortality
[c] Observed incidence at terminal kill
[d] Beneath the control incidence are the P values associated with the trend test. Beneath the dosed group incidence are the P values corresponding to pairwise comparisons between the controls and that dosed group. The life table analysis regards neoplasms in animals dying prior to terminal kill as being (directly or indirectly) the cause of death. The logistic regression tests regard these lesions as nonfatal. The Cochran-Armitage and Fisher exact tests compare directly the overall incidence rates. For all tests, a negative trend or a lower incidence in a dose group is indicated by N.
[e] Not applicable; no neoplasms in animal group

TABLE C4a
Historical Incidence of Liver Neoplasms in Untreated Male B6C3F$_1$ Mice[a]

Study	Incidence in Controls			
	Hepatocellular Adenoma	Hepatocellular Carcinoma	Hepatoblastoma	Hepatocellular Adenoma, Carcinoma, or Hepatoblastoma
Historical Incidence at Southern Research Institute				
C.I. Pigment Red 3	8/50	5/50	0/50	12/50
Ethylene Glycol	9/54	10/54	0/54	19/54
Nitrofurantoin	2/50	9/50	0/50	10/50
o-Nitroanisole	14/50	7/50	0/50	21/50
Polysorbate 80	5/49	11/49	0/49	15/49
Rhodamine 6G	5/49	10/49	0/49	13/49
Roxarsone	9/50	4/50	0/50	12/50
Overall Historical Incidence				
Total	145/865 (16.8%)	122/865 (14.1%)	0/865 (0.0%)	249/865 (28.8%)
Standard deviation	8.2%	7.2%		10.9%
Range	4%-38%	3%-27%		10%-58%

[a] Data as of 3 April 1991

TABLE C4b
Historical Incidence of Harderian Gland Neoplasms in Untreated Male B6C3F$_1$ Mice[a]

Study	Incidence in Controls		
	Adenoma	Carcinoma	Adenoma or Carcinoma
Historical Incidence at Southern Research Institute

TABLE D3
Statistical Analysis of Primary Neoplasms in Female Mice in the 2-Year Feed Study of o-Nitroanisole (continued)

	0 ppm	666 ppm	2,000 ppm	6,000 ppm
All Organs: Benign or Malignant Neoplasms				
Overall rates	39/50 (78%)	44/50 (88%)	47/50 (94%)	28/50 (56%)
Adjusted rates	84.7%	91.6%	100.0%	60.9%
Terminal rates	31/38 (82%)	22/26 (85%)	33/33 (100%)	27/45 (60%)
First incidence (days)	312	331	445	710
Life table tests	P<0.001N	P=0.005	P=0.010	P=0.001N
Logistic regression tests	P<0.001N	P=0.130	P=0.021	P=0.008N
Cochran-Armitage test	P<0.001N			
Fisher exact test		P=0.143	P=0.020	P=0.016N

(T)Terminal sacrifice
[a] Number of neoplasm-bearing animals/number of animals examined. Denominator is number of animals examined microscopically for adrenal gland, bone marrow, brain, clitoral gland, epididymis, gallbladder (mouse), heart, kidney, larynx, liver, lung, nose, ovary, pancreas, parathyroid gland, pituitary gland, preputial gland, prostate gland, salivary gland, spleen, testes, thyroid gland, and urinary bladder; for other tissues, denominator is number of animals necropsied.
[b] Kaplan-Meier estimated neoplasm incidence at the end of the study after adjustment for intercurrent mortality
[c] Observed incidence at terminal kill
[d] Beneath the control incidence are the P values associated with the trend test. Beneath the dosed group incidence are the P values corresponding to pairwise comparisons between the controls and that dosed group. The life table analysis regards neoplasms in animals dying prior to terminal kill as being (directly or indirectly) the cause of death. The logistic regression tests regard these lesions as nonfatal. The Cochran-Armitage and Fisher exact tests compare directly the overall incidence rates. For all tests, a negative trend or a lower incidence in a dose group is indicated by N.
[e] Not applicable; no neoplasms in animal group

TABLE D4
Historical Incidence of Liver Neoplasms in Untreated Female B6C3F$_1$ Mice[a]

Study	Incidence in Controls			
	Hepatocellular Adenoma	Hepatocellular Carcinoma	Hepatoblastoma	Hepatocellular Adenoma, Carcinoma, or Hepatoblastoma
Historical Incidence at Southern Research Institute				
C.I. Pigment Red 3	7/50	4/50	0/50	10/50
Ethylene Glycol	8/50	3/50	0/50	10/50
Nitrofurantoin	1/50	1/50	0/50	2/50
o-Nitroanisole	14/50	5/50	1/50	17/50
Polysorbate 80	2/50	1/50	0/50	3/50
Rhodamine 6G	5/50	3/50	0/50	8/50
Roxarsone	1/50	2/50	0/50	3/50
Overall Historical Incidence				
Total	74/863 (8.6%)	28/863 (3.2%)	1/863 (0.1%)	98/863 (11.4%)
Standard deviation	6.5%	2.9%	0.5%	7.6%
Range	0%-28%	0%-10%	0%-2%	3%-34%

[a] Data as of 3 April 1991

TABLE D5
Summary of the Incidence of Nonneoplastic Lesions in Female Mice in the 2-Year Feed Study of o-Nitroanisole[a]

	0 ppm	666 ppm	2,000 ppm	6,000 ppm
Disposition Summary				
Animals initially in study	60	60	60	60
15-Month interim evaluation	10	10	10	10
Early deaths				
Moribund	7	16	10	5
Natural deaths	5	8	7	
Survivors				
Terminal sacrifice	38	26	33	45

APPENDIX E
SUMMARY OF LESIONS IN MALE RATS IN THE STOP-EXPOSURE FEED STUDY OF *o*-NITROANISOLE

TABLE E1
Summary of the Incidence of Neoplasms in Male Rats in the Stop-Exposure Feed Study of *o*-Nitroanisole[a]

	0 ppm	6,000 ppm	18,000 ppm
Disposition Summary			
Animals initially in study	60	60	60
3-Month interim evaluation	10	10	10
6-Month interim evaluation	10	10	10
9-Month interim evaluation	10	10	6
15-Month interim evaluation	9	3	0
Early deaths			
Moribund	7	26	23
Natural deaths	1		11
Survivors			
Terminal sacrifice	13	1	0
Animals examined microscopically	60	60	60
***3-Month Interim Evaluation*[b]**			
Urinary System			
Urinary bladder	(9)	(9)	(10)
Transitional epithelium, carcinoma			1 (10%)
Neoplasm Summary			
Total animals with primary neoplasms[b]			1
Total primary neoplasms			1
Total animals with malignant neoplasms			1
Total malignant neoplasms			1
***6-Month Interim Evaluation*[b]**			
Alimentary System			
Intestine large, colon			(3)
Polyp adenomatous			2 (67%)
Stomach, forestomach		(2)	
Papilloma squamous		1 (50%)	
Urinary System			
Urinary bladder	(10)	(10)	(10)
Sarcoma			2 (20%)
Transitional epithelium, carcinoma			10 (100%)
Transitional epithelium, papilloma		2 (20%)	
Neoplasm Summary			
Total animals with primary neoplasms		3	10
Total primary neoplasms		3	14
Total animals with benign neoplasms		3	2
Total benign neoplasms		3	2
Total animals with malignant neoplasms			10
Total malignant neoplasms			12

TABLE E1
Summary of the Incidence of Neoplasms in Male Rats in the Stop-Exposure Feed Study of *o*-Nitroanisole (continued)

Overall rate	21/21 (100%)	27/27 (100%)	34/34 (100%)
Adjusted rate	100.0%	100.0%	100.0%
Terminal rate	13/13 (100%)	1/1 (100%)	0/0 (0%)
First incidence (days)	410	207	158
Life table test	P<0.001	P<0.001	P<0.001
Cochran-Armitage test	–		
Fisher exact test		P=1.000N	P=1.000N

(T)Terminal sacrifice
[a] Number of neoplasm-bearing animals/number of animals examined. Denominator is number of animals examined microscopically for adrenal gland, bone marrow, brain, clitoral gland, epididymis, gallbladder (mouse), heart, kidney, larynx, liver, lung, nose, ovary, pancreas, parathyroid gland, pituitary gland, preputial gland, prostate gland, salivary gland, spleen, testes, thyroid gland, and urinary bladder; for other tissues, denominator is number of animals necropsied.
[b] Kaplan-Meier estimated neoplasm incidence at the end of the study after adjustment for intercurrent mortality
[c] Observed incidence at terminal kill
[d] Beneath the control incidence are the P values associated with the trend test. Beneath the dosed group incidence are the P values corresponding to pairwise comparisons between the controls and that dosed group. The life table analysis regards neoplasms in animals dying prior to terminal kill as being (directly or indirectly) the cause of death. The Cochran-Armitage and Fisher exact tests compare directly the overall incidence rates. For all tests, a negative trend or a lower incidence in a dose group is indicated by N.
[e] Not applicable; no neoplasms in animal group
[f] Value of statistic cannot be computed

TABLE E4
Summary of the Incidence of Nonneoplastic Lesions in Male Rats in the Stop-Exposure Feed Study of *o*-Nitroanisole[a]

	0 ppm	6,000 ppm	18,000 ppm
Disposition Summary			
Animals initially in study	60	60	60
3-Month interim evaluation	10	10	10

Renal tubule, pigmentation	20 (95%)	26 (96%)	34 (100%)
Renal tubule, regeneration		2 (7%)	6 (18%)
Transitional epithelium, hemorrhage			1 (3%)
Transitional epithelium, hyperplasia	5 (24%)	24 (89%)	19 (56%)
Ureter	(19)	(25)	(34)
Dilatation		4 (16%)	14 (41%)
Hemorrhage			1 (3%)
Inflammation, chronic			1 (3%)
Transitional epithelium, hyperplasia		1 (4%)	
Urethra		(2)	(1)
Bulbourethral gland, cyst, multiple		1 (50%)	
Transitional epithelium, hyperplasia			1 (100%)
Urinary bladder	(21)	(27)	(34)
Hemorrhage		1 (4%)	6 (18%)
Inflammation, suppurative			4 (12%)
Metaplasia, squamous		3 (11%)	30 (88%)
Necrosis		1 (4%)	
Transitional epithelium, hyperplasia		9 (33%)	2 (6%)
Wall, proliferation connective tissue		1 (4%)	24 (71%)

[a] Number of animals examined microscopically at site and number of animals with lesion.

APPENDIX F
SUMMARY OF LESIONS IN FEMALE RATS IN THE STOP-EXPOSURE FEED STUDY OF *o*-NITROANISOLE

TABLE F1
Summary of the Incidence of Neoplasms in Female Rats in the Stop-Exposure Feed Study of *o*-Nitroanisole[a]

	0 ppm	6,000 ppm	18,000 ppm
Disposition Summary			
Animals initially in study	60	60	60
3-Month interim evaluation	10	10	10
6-Month interim evaluation	10	10	10
9-Month interim evaluation	10	10	6
15-Month interim evaluation	8	10	0
Early deaths			
Moribund	6	12	25
Natural deaths	2	4	9
Survivors			
Terminal sacrifice	14	4	0
Animals examined microscopically	60	60	60
***3-Month Interim Evaluation*[b]**			
***6-Month Interim Evaluation*[b]**			
Alimentary System			
Intestine large, colon		(1)	
Polyp adenomatous		1 (100%)	
Urinary System			
Urinary bladder	(10)	(10)	(10)
Transitional epithelium, carcinoma			10 (100%)
Neoplasm Summary			
Total animals with primary neoplasms[c]		1	10
Total primary neoplasms		1	10
Total animals with benign neoplasms		1	
Total benign neoplasms		1	
Total animals with malignant neoplasms			10
Total malignant neoplasms			10
***9-Month Interim Evaluation*[b]**			
Alimentary system			
Intestine large, colon			(1)
Polyp adenomatous, multiple			1 (100%)
Urinary System			
Urinary bladder	(10)	(9)	(6)
Sarcoma			2 (33%)
Transitional epithelium, carcinoma		1 (11%)	6 (100%)

TABLE F1
Summary of the Incidence of Neoplasms in Female Rats in the Stop-Exposure Feed Study of *o*-Nitroanisole (continued)

	0 ppm	6,000 ppm	18,000 ppm
9-Month Interim Evaluation (continued)			
Neoplasm Summary			
Total animals with primary neoplasms		1	6
Total primary neoplasms		1	9
Total animals with benign neoplasms			1
Total benign neoplasms			1
Total animals with malignant neoplasms		1	6
Total malignant neoplasms		1	8
15-Month Interim Evaluation			
Alimentary System			
Intestine large, colon		(2)	
Polyp adenomatous, multiple		2 (100%)	
Intestine large, rectum		(2)	
Polyp adenomatous		1 (50%)	
Cardiovascular System			
None			
Endocrine System			
Pituitary gland		(1)	
Pars distalis, adenoma		1 (100%)

Squamous cell carcinoma			1 (3%)
Squamous cell papilloma			2 (6%)
Squamous cell papilloma, multiple			2 (6%)
Transitional epithelium, carcinoma		18 (90%)	32 (94%)
Transitional epithelium, papilloma		1 (5%)	
Transitional epithelium, papilloma, multiple			1 (3%)
Systemic Lesions			
Multiple organs[d]	(22)	(20)	(34)
Leukemia mononuclear	3 (14%)		

TABLE F1
Summary of the Incidence of Neoplasms in Female Rats in the Stop-Exposure Feed Study of *o*-Nitroanisole (continued)

	0 ppm	6,000 ppm	18,000 ppm
Stop-Exposure Study (continued)			
Neoplasm Summary			
Total animals with primary neoplasms	20	20	32
Total primary neoplasms	34	43	76
Total animals with benign neoplasms	16	14	21
Total benign neoplasms	24	20	27
Total animals with malignant neoplasms	10	20	32
Total malignant neoplasms	10	23	49
Total animals with metastatic neoplasms			3
Total metastatic neoplasm			17

[a] Number of animals examined microscopically at site and number of animals with lesion.
[b] All organ systems listed in Table 1 (Materials and Methods) were evaluated, but neoplasms were found only in systems specified.
[c] Primary neoplasms: all neoplasms except metastatic neoplasms
[d] Number of animals with any tissue examined microscopically

(T)Terminal sacrifice
[a] Number of neoplasm-bearing animals/number of animals examined. Denominator is number of animals examined microscopically for adrenal gland, bone marrow, brain, clitoral gland, epididymis, gallbladder (mouse), heart, kidney, larynx, liver, lung, nose, ovary, pancreas, parathyroid gland, pituitary gland, preputial gland, prostate gland, salivary gland, spleen, testes, thyroid gland, and urinary bladder; for other tissues, denominator is number of animals necropsied.
[b] Kaplan-Meier estimated neoplasm incidence at the end of the study after adjustment for intercurrent mortality
[c] Observed incidence at terminal kill
[d] Beneath the control incidence are the P values associated with the trend test. Beneath the dosed group incidence are the P values corresponding to pairwise comparisons between the controls and that dosed group. The life table analysis regards neoplasms in animals dying prior to terminal kill as being (directly or indirectly) the cause of death. The logistic regression test regards these lesions as nonfatal. The Cochran-Armitage and Fisher exact tests compare directly the overall incidence rates. For all tests, a negative trend or a lower incidence in a dose group is indicated by N.
[e] Not applicable; no neoplasms in animal group

APPENDIX G
GENETIC TOXICOLOGY

GENETIC TOXICOLOGY

SALMONELLA PROTOCOL

Testing was performed as reported by Haworth *et al.* (1983). *o*-Nitroanisole was sent to the laboratory as a coded aliquot from Radian Corporation (Austin, TX). It was incubated with the *Salmonella typhimurium* tester strains (TA100, TA1535, TA1537, TA98, and TA97) either in buffer or S9 mix (metabolic activation enzymes and cofactors from Aroclor 1254-induced male Sprague-Dawley rat or Syrian hamster liver) for 20 minutes at 37° C prior to the addition of soft agar supplemented with *l*-histidine and *d*-biotin, and subsequent plating on minimal glucose agar plates. Incubation continued for an additional 48 hours.

Each trial consisted of triplicate plates of concurrent positive and negative controls and of at least five doses of *o*-nitroanisole. High dose was limited by toxicity. All positive assays were repeated under the conditions which elicited the positive response.

In this assay, a positive response is defined as a reproducible, dose-related increase in histidine-independent (revertant) colonies in any one strain/activation combination. An equivocal response is defined as an increase in revertants which was not dose related, not reproducible, or of insufficient magnitude to support a determination of mutagenicity. A negative response was obtained when no increase in revertant colonies was observed following chemical treatment.

CHINESE HAMSTER OVARY CYTOGENETICS ASSAYS

Testing was performed as reported by Galloway *et al.* (1985, 1987) and presented briefly below. *o*-Nitroanisole was sent to the laboratory as a coded aliquot from Radian Corporation (Austin, TX). It was tested in cultured Chinese hamster ovary (CHO) cells for induction of sister chromatid exchanges (SCE) and chromosomal aberrations (Abs) both in the presence and absence of Aroclor 1254-induced male Sprague-Dawley rat liver S9 and cofactor mix. Cultures were handled under gold lights to prevent photolysis of bromodeoxyuridine (BrdU)-substituted DNA. Each test consisted of concurrent solvent and positive controls and of at least three doses of *o*-nitroanisole; the high dose was limited by solubility.

In the SCE test without S9, CHO cells were incubated for 26 hours with *o*-nitroanisole in McCoy's 5A medium supplemented with 10% fetal bovine serum, *l*-glutamine (2mM), and antibiotics. BrdU was added 2 hours after culture initiation. After 26 hours, the medium containing *o*-nitroanisole was removed and replaced with fresh medium plus BrdU and Colcemid, and incubation was continued for 1.5 hours. Cells were then harvested by mitotic shake-off, fixed, and stained with Hoechst 33258 and Giemsa. In the SCE test with S9, cells were incubated with *o*-nitroanisole, serum-free medium, and S9 for 2 hours. The medium was then removed and replaced with medium containing BrdU and no *o*-nitroanisole and incubation proceeded for an additional 25.5 hours, with Colcemid present for the final 2 to 3 hours. Harvesting and staining was the same as for cells treated without S9.

In the chromosomal Abs test without S9, cells were incubated in McCoy's 5A medium with *o*-nitroanisole for 8 hours; Colcemid was added and incubation continued for 2 to 3 hours. The cells were then harvested by mitotic shake-off, fixed, and stained with Giemsa. For the Abs test with S9, cells were treated with *o*-nitroanisole and S9 for 2 hours, after which the treatment medium was removed and the cells incubated for 9 hours in fresh medium, with Colcemid present for the final 2 to 3 hours. Cells were harvested in the same manner as for the treatment without S9.

For the SCE test, because significant chemical-induced cell cycle delay was seen at some dose levels, incubation time was lengthened at these dose levels to ensure a sufficient number of scorable cells.

Cells were selected for scoring on the basis of good morphology and completeness of karyotype (21 ± 2 chromosomes). All slides were scored blind and those from a single test were read by the same person. For the SCE test, usually 50 second-division metaphase cells were scored for frequency of SCE per cell from each dose level; 100 first-division metaphase cells were scored at each dose level for the Abs test. Classes of aberrations included simple (breaks and terminal deletions), complex (rearrangements and translocations), and other (pulverized cells, despiralized chromosomes, and cells containing ten or more aberrations).

Statistical analyses were conducted on both the slopes of the dose-response curves and the individual dose points. An SCE frequency 20% above the concurrent solvent control value was chosen as a statistically conservative positive response. The probability of this level of difference occurring by chance at one dose point is less than 0.01; the probability for such a chance occurrence at two dose points is less than 0.001. A single increased dose was considered weak evidence of a positive response (+w); two increased doses were sufficient to evaluate the trial as positive (+). Chromosomal Abs data are presented as percentage of cells with aberrations. Both the dose-response curve and individual dose points were statistically analyzed. A statistically significant ($P<0.05$) difference for one dose point was considered weak evidence for a positive response (+w); significant differences for two or more doses indicated the trial was positive (+) (Galloway *et al.*, 1987).

Mouse Lymphoma Protocol

The experimental protocol is presented in detail by Myhr *et al.* (1985) *o*-Nitroanisole was supplied as a coded aliquot by Radian Corporation (Austin, TX). The highest dose of *o*-nitroanisole was determined by solubility or toxicity. Mouse L5178Y lymphoma cells were maintained at 37° C as suspension cultures in Fischer's medium supplemented with *l*-glutamine, sodium pyruvate, pluronic F68, antibiotics, and heat-inactivated horse serum; normal cycling time was about 10 hours. To reduce the number of spontaneously occurring trifluorothymidine (TFT)-resistant cells, subcultures were exposed once to medium containing THMG (thymidine, hypoxanthine, methotrexate, glycine) for 1 day, to THG for 1 day, and to normal medium for 3 to 5 days. For cloning, horse serum content was increased and Noble agar was added.

All treatment levels within an experiment, including concurrent positive and solvent controls, were replicated. Treated cultures contained 6×10^6 cells. Incubation with *o*-nitroanisole continued for 4 hours, at which time the medium plus *o*-nitroanisole was removed and the cells were resuspended in fresh medium and incubated for an additional 2 days to express the mutant phenotype. Cell density was monitored so that log phase growth was maintained. After the 48-hour expression period, 3×10^6 cells were plated in medium and soft agar supplemented with trifluorothimydine for selection of TFT-resistant cells ($TK^{-/-}$), and 600 cells were plated in nonselective medium and soft agar to determine cloning efficiency. Plates were incubated at 37° C in 5% CO_2 for 10 to 12 days. All data were evaluated statistically for both trend and peak response. Both responses had to be significant ($P<0.05$) for *o*-nitroanisole to be considered capable of inducing TFT resistance; a single significant response led to a "questionable" conclusion, and the absence of both a trend and a peak response resulted in a "negative" call. An inconclusive test was one in which no significant response was observed at any of the doses tested, but, based on the relative total growth (RTG) values, it was apparent that higher doses could have been used.

Minimum criteria for accepting an experiment as valid and a detailed description of the statistical analysis and data evaluation are presented in Myhr *et al.* (1985). This assay is initially performed without S9; because a clearly positive response was obtained, *o*-nitroanisole was not tested with S9.

RESULTS

o-Nitroanisole was tested in a preincubation protocol in two laboratories for induction of gene mutations in four strains of *Salmonella typhimurium* in the presence and the absence of Aroclor 1254-induced male Sprague-Dawley rat or Syrian hamster liver S9 (Table G1). In the first study (Haworth *et al.*, 1983), concentrations of 33 to 2,150 μg/plate were tested in strains TA100, TA1535, TA1537, and TA98; positive responses were observed only in strain TA100, with and without S9. In the second study, strains TA100, TA1535, TA97, and TA98 were tested (top dose, 3,333 μg/plate); positive responses were again noted for TA100, with and without S9, and also for TA1535, without S9. Both these strains mutate via base-substitution. In cytogenetic tests with CHO cells, *o*-nitroanisole induced SCEs with and without Aroclor 1254-induced male Sprague-Dawley rat liver S9 (Table G2; Galloway *et al.*, 1987); at higher doses (above 123 μg/mL without S9, and above 811 μg/mL with S9), delayed harvest was used to offset *o*-nitroanisole-induced cell cycle delay and allow for accumulation of sufficient metaphases for analysis. In the CHO cell chromosomal Abs test (Table G3; Galloway *et al.*, 1987), *o*-nitroanisole induced a significant increase in Abs at the highest dose (1,060 μg/mL) tested in the presence of S9 activation; this response was due mainly to an increase in breaks which occurred in the long arm of the X chromosome. No increase in Abs was observed in either of the two trials conducted without S9. *o*-Nitroanisole was positive in the mouse lymphoma L5178Y cell assay for induction of TFT resistance in the absence of S9 activation; it was not tested with S9 (Table G4). The first of three trials was considered inconclusive because a negative response was obtained at the highest nonlethal dose tested, but the relative total growth was not markedly decreased. In the remaining two trials, a dose-related increase in TFT-resistant colonies was observed and significant responses occurred at doses where the relative total growth was depressed below 50%.

[a] The detailed protocol as well as the data from the EG&G Mason Research Institute study are presented in Haworth *et al.* (1983). Cells and *o*-nitroanisole or solvent (dimethylsulfoxide) were incubated in the absence of exogenous metabolic activation (-S9) or with Aroclor 1254-induced S9 from male Syrian hamster liver or male Sprague-Dawley rat liver. The high dose was limited by toxicity; 0 μg/plate dose is the solvent control.

[b] Revertants are presented as mean ± standard error from three plates.

[c] Slight toxicity

[d] 2-aminoanthracene was used on all strains in the presence of S9. In the absence of metabolic activation, 4-nitro-*o*-phenylenediamine was tested on TA98, sodium azide was tested on TA100 and TA1535, and 9-aminoacridine was tested on TA1537.

TABLE G2
Induction of Sister Chromatid Exchanges in Chinese Hamster Ovary Cells by *o*-Nitroanisole (continued)

° Positive (>20% increase over solvent control)
[a] Study performed at Litton Bionetics, Inc. SCE = sister chromatid exchange; BrdU = bromodeoxyuridine. A detailed description of the SCE protocol and these data are presented in Galloway *et al.* (1987). Briefly, Chinese hamster ovary cells were incubated with *o*-nitroanisole or solvent (dimethylsulfoxide) as described in [c] and [f] below, and cultured for sufficient time to reach second metaphase division. Cells were then collected by mitotic shake-off, fixed, air-dried, and stained.
[b] SCEs/chromosome of culture exposed to *o*-nitroanisole relative to those of culture exposed to solvent.
[c] In the absence of S9, cells were incubated with *o*-nitroanisole or solvent for 2 hours at 37° C. Then BrdU was added and incubation was continued for 24 hours. Cells were washed, fresh medium containing BrdU and Colcemid was added, and incubation was continued for 1.5 hours.
[d] Significance of relative SCEs/chromosome tested by the linear regression trend test vs. log of the dose
[e] Because *o*-nitroanisole-induced cell cycle delay was observed, harvest time was extended to maximize the proportion of second division cells available for analysis.
[f] In the presence of S9, cells were incubated with *o*-nitroanisole or solvent for 2 hours at 37° C. The cells were then washed, and medium containing BrdU was added. Cells were incubated for a further 25.5 hours, with Colcemid present for the final 2 to 3 hours. S9 was from the livers of Aroclor 1254-induced male Sprague-Dawley rats.
[g] Precipitate formed at all dose levels in this trial.

* Positive (P<0.05)

[a] Study performed at Litton Bionetics, Inc. Abs = aberrations. A detailed presentation of the technique for detecting chromosomal aberrations and these data are found in Galloway *et al.* (1987). Briefly, Chinese hamster ovary cells were incubated with *o*-nitroanisole or solvent (dimethylsulfoxide) as indicated in [b] and [c]. Cells were arrested in first metaphase by addition of Colcemid and harvested by mitotic shake-off, fixed, and stained in 6% Giemsa.

[b] In the absence of S9, cells were incubated with *o*-nitroanisole or solvent for 8 hours at 37° C. Cells were then washed and fresh medium containing Colcemid was added for an additional 2 to 3 hours followed by harvest.

[c] In the presence of S9, cells were incubated with *o*-nitroanisole or solvent for 2 hours at 37° C. Cells were then washed, medium was added, and incubation was continued for 9 hours. Colcemid was added for the last 2 to 3 hours of incubation before harvest. S9 was from the livers of Aroclor 1254-induced male Sprague-Dawley rats.

[d] Significance of percent cells with aberrations tested by the linear regression trend test vs. log of the dose

[e] Precipitate formed at all dose levels in this trial.

[a] Study performed at Litton Bionetics, Inc. The experimental protocol is presented in detail by Myhr *et al.* (1985). The highest dose of *o*-nitroanisole is determined by solubility or toxicity. All doses are tested in triplicate; the average of the three tests is presented in the table. Cells (6×10^5/mL) were treated for 4 hours at 37° C in medium, washed, resuspended in medium, and incubated for 48 hours at 37° C. After expression, 3×10^6 cells were plated in medium and soft agar supplemented with trifluorothymidine for selection of cells that were mutant at the thymidine kinase (TK) locus, and 600 cells were plated in nonselective medium and soft agar to determine the cloning efficiency.

[b] Mutant fraction (frequency) is a ratio of the mutant count to the cloning efficiency, divided by 3 (to arrive at MF/10^6 cells treated).

[c] Significant positive response ($P<0.05$)

[d] Precipitation

APPENDIX J
CHEMICAL CHARACTERIZATION AND DOSE FORMULATION STUDIES

CHEMICAL CHARACTERIZATION AND DOSE FORMULATION STUDIES

PROCUREMENT AND CHARACTERIZATION OF *o*-NITROANISOLE

o-Nitroanisole was obtained from Aldrich Chemical Company (Milwaukee, WI) in three lots (lot TE061197, lot 2712DL, and lot 1517AM). Lot TE061197 was used throughout the 14-day and 13-week studies in rats and mice and in a portion of the stop-exposure and 2-year studies in rats. Lot 2712DL was used in a portion of the stop-exposure study in rats and the 2-year studies in rats and mice; lot 1517AM was used in a portion of the 2-year studies in rats and mice. Identity, purity, and stability analyses were conducted by the analytical chemistry laboratory, Midwest Research Institute (MRI; Kansas City, MO). MRI reports on analyses performed in support of the *o*-nitroanisole studies are on file at the National Institute of Environmental Health Sciences.

All three lots of the chemical, a clear yellow liquid, were identified as *o*-nitroanisole by infrared, ultraviolet/visible, and nuclear magnetic resonance spectroscopy. All spectra were consistent with those expected for the structure and with the literature spectra of *o*-nitroanisole (*Sadtler Standard Spectra*), as shown in Figures J1 and J2.

The purity of all lots was determined by Karl Fischer water analysis, elemental analyses, titration, thin-layer chromatography (TLC), and gas chromatography. Titration was performed by reducing the nitro group with titanous chloride in a glacial acetic acid:hydrochloric acid:hydrofluoric acid medium followed by back-titration of the excess titanous chloride with 0.25 N ferric ammonium sulfate. Titration was monitored potentiometrically with a platinum foil indicator electrode versus a silver/silver chloride reference electrode. TLC was performed on Silica Gel 60 F-254 plates with two solvent systems: 1) toluene and 2) methylene chloride. Plates were examined under shortwave (254 nm) and longwave (366 nm) ultraviolet light and a spray of 5% titanous chloride. Gas chromatographic analysis was performed with a flame ionization detector (FID) with a nitrogen carrier gas at a flow rate of 70 mL/minute. Two systems were used: A) 10% SP-2100 on 80/100 Supelcoport, with an oven temperature program of 50° C for 5 minutes, then 50° to 250° C at 10° C per minute, and B) 10% Carbowax 20M/TPA on 80/100 Chromosorb W(AW) with an oven temperature program of 60° C for 6 minutes, then 60° to 200° C at 10° C per minute.

Elemental analyses of lot TE061197 for carbon, hydrogen, and nitrogen were in agreement with the theoretical values for *o*-nitroanisole. Karl Fischer water analysis indicated 0.238 ± 0.008% water. Titration indicated a purity of at least 97%. Each TLC system indicated only a major spot. Gas chromatography using the first system indicated a major peak and one impurity with a total area of less than 0.3% relative to the major peak. A major peak with no impurities with areas greater than or equal to 0.1% of the major peak area was observed with the second column. The overall purity was determined to be approximately 99%.

Lot 2712DL was received in two shipments, which were analyzed separately. For the first batch, elemental analyses for carbon, hydrogen, and nitrogen were in agreement with the theoretical values for *o*-nitroanisole. Karl Fischer water analysis indicated 0.091 ± 0.003% water. Titration indicated a purity of at least 97%. Each TLC system indicated only a major spot. Gas chromatography using the first system indicated a major peak and three impurities with a total area of 0.4% relative to the major peak. A major peak and two impurities with a total area of 0.3% relative to the major peak was observed with the second system. For the second batch, elemental analyses for carbon were slightly low, while values for hydrogen and nitrogen were in agreement with the theoretical values for *o*-nitroanisole. Titration indicated a purity of at least 96%. Each TLC system indicated only a major spot. Gas chromatography using both systems indicated a major peak and two impurities with a total area of 0.3% relative to the major peak. A concomitant analysis of lot TE061197 using gas chromatography indicated a major peak and one impurity

with an area of 0.1% relative to the major peak by system A. The second system indicated a major peak and one impurity with an area of 0.1% relative to the major peak. The overall purity of this batch of lot 2712DL was determined to be approximately 99%, which is consistent with lot TE061197.

Elemental analyses of lot 1517AM for carbon, hydrogen, and nitrogen were in agreement with the theoretical values for *o*-nitroanisole. Karl Fischer water analysis indicated 0.037 ± 0.002% water. Titration indicated a purity of at least 98%. Each TLC system indicated one major spot and no impurities. Gas chromatography using system A indicated a major peak and three impurities with a total area of 0.67% relative to the major peak. A major peak and three impurities with a total area of 0.56% relative to the major peak was observed with system B as described above, but with an oven temperature program of 60° C for 6 minutes, then 60° to 225° C at 10° C per minute. A concomitant analysis of lot TE061197 with lot 1517AM by gas chromatography using system A, but with an oven temperature of 180° C, and with pentadecane added as an internal standard, gave a relative purity of approximately 100% for lot 1517AM relative to lot TE061197.

Stability studies were performed by the analytical chemistry laboratory on lot TE061197. Gas chromatography was performed using system A described above, but with *n*-pentadecane added as an internal standard and an oven temperature of 180° C. These studies indicated that *o*-nitroanisole was stable as a bulk chemical for at least 2 weeks at temperatures up to 60° C. The stability of the bulk chemical was monitored periodically at the study laboratory with infrared and ultraviolet/visible spectroscopy and gas chromatography methods similar to those described above. No degradation of the bulk chemical was observed.

Preparation and Analysis of Dose Formulations

The dose formulations were prepared by mixing the appropriate amounts of *o*-nitroanisole and feed in a blender (Patterson-Kelley Twin Shell with intensifier bar) for 15 minutes (Table J1). Studies to determine homogeneity and stability of the dosed feed preparations were conducted by the analytical chemistry laboratory. For homogeneity analyses, feed samples were extracted with 100 mL of acetonitrile, centrifuged, and further diluted with acetonitrile. The absorbance of the samples was measured versus acetonitrile by ultraviolet spectroscopy at 325 nm. For the stability studies, feed samples were extracted with 100 mL of 0.25 N hydrochloric acid in acetonitrile, centrifuged, and further diluted with acetonitrile. The samples were then injected into a high-performance liquid chromatographic system equipped with a μBondpak C_{18} column. The mobile phase was a mixture of water:acetonitrile at a ratio of 60:40 and a flow rate of 1 mL/minute. Ultraviolet detection was at 254 nm. Homogeneity was confirmed and the stability of the dose formulations was established for at least 2 weeks when stored in the dark at temperatures up to 25° C and for 1 week when stored open to air and light.

Periodic analyses of the dose formulations of *o*-nitroanisole were conducted at the study laboratory and the analytical chemistry laboratory using an ultraviolet spectroscopic method as well as two HPLC methods. During the 14-day studies, the dose formulations were analyzed at the beginning of the studies (Table J2). During the 13-week studies, the dose formulations were analyzed at the initiation, midpoint, and termination of the studies (Table J3). In both the 14-day and 13-week studies, an ultraviolet spectroscopic method that required an acetonitrile extraction was used.

During the 2-year studies, the dose formulations were analyzed at least once every 8 weeks using two HPLC methods (Table J4). The two methods differed primarily in the extraction and clean-up procedures. The earlier subchronic studies had demonstrated that *o*-nitroanisole binds strongly to feed; it was also observed that the analytical recovery was time dependent so that the longer the chemical stayed in contact with the feed, the lower the recovery. The first method used to overcome this problem involved an elaborate extraction and clean-up procedure. The feed formulations were first digested with approximately 8 N hydrochloric acid, diluted with ethanol, and then extracted with petroleum ether:ethyl ether (1:1). After evaporation to dryness, the oily residue was dissolved in corn oil, and the corn oil solution was then

extracted with acetonitrile. Prior to the injection into the HPLC, the acetonitrile extract was diluted with water and filtered. The complexity of the first method contributed to periodic analysis problems. During the second year of the 2-year study, the extraction and clean-up method was simplified. In the modified procedure, the untreated feed formulations were extracted directly with 0.25 N hydrochloric acid in acetonitrile; the extracts were then neutralized with sodium hydroxide and injected into the HPLC. The method was limited by the requirement that the analyses had to be conducted immediately after the dose formulations were prepared. The change was worthwhile because during the remainder of the studies only three formulations were outside of the specifications. While the analytical recovery problem was overcome by the immediate analysis of the feed formulations, there was concern that the bioavailability of *o*-nitroanisole would be affected by the physical binding to feed. In a subsequent separate study, it was demonstrated that the physical binding of *o*-nitroanisole to feed did not affect its bioavailability (Yuan *et al.*, 1991).

In the stop-exposure and 2-year studies, 85% (141/166) of the dose formulations were within ± 10% of the target concentrations. Results of the periodic referee analyses performed by the analytical chemistry laboratory were in good agreement with the results obtained by the study laboratory (Table J5).

[a] Grams of feed consumed per animal per day
[b] Milligrams of *o*-nitroanisole consumed per day per kilogram body weight

APPENDIX L
INGREDIENTS, NUTRIENT COMPOSITION, AND CONTAMINANT LEVELS IN NIH-07 RAT AND MOUSE RATION

TABLE L1
Ingredients of NIH-07 Rat and Mouse Ration[a]

Ingredients[b]	Percent by Weight
Ground #2 yellow shelled corn	24.50
Ground hard winter wheat	23.00
Soybean meal (49% protein)	12.00
Fish meal (60% protein)	10.00
Wheat middlings	10.00
Dried skim milk	5.00
Alfalfa meal (dehydrated, 17% protein)	4.00
Corn gluten meal (60% protein)	3.00
Soy oil	2.50
Dried brewer's yeast	2.00
Dry molasses	1.50
Dicalcium phosphate	1.25
Ground limestone	0.50
Salt	0.50
Premixes (vitamin and mineral)	0.25

[a] NCI, 1976; NIH, 1978
[b] Ingredients were ground to pass through a U.S. Standard Screen No. 16 before being mixed.

TABLE L2
Vitamins and Minerals in NIH-07 Rat and Mouse Ration[a]

	Amount	Source
Vitamins		
A	5,500,000 IU	Stabilized vitamin A palmitate or acetate
D_3	4,600,000 IU	D-activated animal sterol
K_3	2.8 g	Menadione
d-α-Tocopheryl acetate	20,000 IU	
Choline	560.0 g	Choline chloride
Folic acid	2.2 g	
Niacin	30.0 g	
d-Pantothenic acid	18.0 g	*d*-Calcium pantothenate
Riboflavin	3.4 g	
Thiamine	10.0 g	Thiamine mononitrate
B_{12}	4,000 µg	
Pyridoxine	1.7 g	Pyridoxine hydrochloride
Biotin	140.0 mg	*d*-Biotin
Minerals		
Iron	120.0 g	Iron sulfate
Manganese	60.0 g	Manganous oxide
Zinc	16.0 g	Zinc oxide
Copper	4.0 g	Copper sulfate
Iodine	1.4 g	Calcium iodate
Cobalt	0.4 g	Cobalt carbonate

[a] Per ton (2,000 lb) of finished product

TABLE L3
Nutrient Composition of NIH-07 Rat and Mouse Ration

Nutrient	Mean ± Standard Deviation	Range	Number of Samples
Protein (% by weight)	22.32 ± 0.57	21.2–23.2	25
Crude fat (% by weight)	5.60 ± 0.44	4.6–6.4	25
Crude fiber (% by weight)	3.54 ± 0.54	2.8–5.4	25
Ash (% by weight)	6.62 ± 0.44	6.0–7.9	25
Amino Acids (% of total diet)			
Arginine	1.308 ± 0.060	1.210–1.390	8
Cystine	0.306 ± 0.084	0.181–0.400	8
Glycine	1.150 ± 0.047	1.060–1.210	8
Histidine	0.576 ± 0.024	0.531–0.607	8
Isoleucine	0.917 ± 0.029	0.881–0.944	8
Leucine	1.946 ± 0.055	1.850–2.040	8
Lysine	1.270 ± 0.058	1.200–1.370	8
Methionine	0.448 ± 0.128	0.306–0.699	8
Phenylalinine	0.987 ± 0.140	0.665–1.110	8
Threonine	0.877 ± 0.042	0.824–0.940	8
Tryptophan	0.236 ± 0.176	0.107–0.671	8
Tyrosine	0.676 ± 0.105	0.564–0.794	8
Valine	1.103 ± 0.040	1.050–1.170	8
Essential Fatty Acids (% of total diet)			
Linoleic	2.393 ± 0.258	1.830–2.570	7
Linolenic	0.280 ± 0.040	0.210–0.320	7
Vitamins			
Vitamin A (IU/kg)	9,212 ± 4,047	4,500–19,000	25
Vitamin D (IU/kg)	4,450 ± 1,382	3,000–6,300	4
α-Tocopherol (ppm)	37.95 ± 9.406	22.50–48.90	8
Thiamine (ppm)	21.76 ± 3.41	19.0–37.0	25
Riboflavin (ppm)	7.92 ± 0.87	6.10–9.00	8
Niacin (ppm)	103.38 ± 26.59	65.0–150.0	8
Pantothenic acid (ppm)	29.54 ± 3.60	23.0–34.0	8
Pyridoxine (ppm)	9.55 ± 3.48	5.60–14.0	8
Folic acid (ppm)	2.25 ± 0.73	1.80–3.70	8
Biotin (ppm)	0.254 ± 0.042	0.19–0.32	8
Vitamin B_{12} (ppb)	38.45 ± 22.01	10.6–65.0	8
Choline (ppm)	3,089 ± 328.69	2,400–3,430	8
Minerals			
Calcium (%)	1.12 ± 0.13	0.87–1.40	25
Phosphorus (%)	0.93 ± 0.06	0.81–1.00	25
Potassium (%)	0.883 ± 0.078	0.772–0.971	6
Chloride (%)	0.526 ± 0.092	0.380–0.635	8
Sodium (%)	0.313 ± 0.390	0.258–0.371	8
Magnesium (%)	0.168 ± 0.010	0.151–0.181	8
Sulfur (%)	0.280 ± 0.064	0.208–0.420	8
Iron (ppm)	360.54 ± 100	255.0–523.0	8
Manganese (ppm)	91.97 ± 6.01	81.70–99.40	8
Zinc (ppm)	54.72 ± 5.67	46.10–64.50	8
Copper (ppm)	11.06 ± 2.50	8.090–15.39	8
Iodine (ppm)	3.37 ± 0.92	1.52–4.13	6
Chromium (ppm)	1.79 ± 0.36	1.04–2.09	8
Cobalt (ppm)	0.681 ± 0.14	0.490–0.780	4

TABLE L4
Contaminant Levels in NIH-07 Rat and Mouse Ration

	Mean ± Standard Deviation[a]	Range	Number of Samples
Contaminants			
Arsenic (ppm)	0.74 ± 0.16	0.22–0.98	25
Cadmium (ppm)	0.10 ± 0.20	<0.10–0.20	25
Lead (ppm)	0.47 ± 0.20	0.05–0.87	25
Mercury (ppm)[b]	0.05 ± 0.01	0.05–0.08	25

TABLE L4
Contaminant Levels in NIH-07 Rat and Mouse Ration (continued)

[a] For values less than the limit of detection, the detection limit is given as the mean.
[b] Mean, standard deviation, and range include one value of 0.08 ppm. All other values are less than 0.05 ppm.
[c] Sources of contamination - soy oil and fish meal.
[d] CFU = colony forming units.
[e] MPN = most probable number.
[f] Mean, standard deviation, and range include one large value of 150 MPN/g obtained in batch milled 17 October 1984.
[g] Mean, standard deviation, and range include value given in [f].
[h] All values were corrected for percent recovery.
[i] BHC = hexachlorocyclohexane or benzene hexachloride
[j] Ten lots contained more than 0.05 ppm, including one with 3.20 ppm milled 7 May 1985.

APPENDIX M
SENTINEL ANIMAL PROGRAM

SENTINEL ANIMAL PROGRAM

METHODS

Rodents used in the Carcinogenesis Program of the National Toxicology Program are produced in optimally clean facilities to eliminate potential pathogens that may affect study results. The Sentinel Animal Program is part of the periodic monitoring of animal health that occurs during the toxicologic evaluation of chemical compounds. The sentinel animals come from the same production source and weanling groups as animals used for the studies of chemical compounds, and these animals and the study animals are subject to identical environmental conditions.

Serum samples were collected from randomly selected rats and mice during the 14-day, 13-week, and 2-year studies, and rats during the stop-exposure study. Blood from each animal was collected from the orbital sinus, allowed to clot, and the serum separated. The serum was cooled and sent to Microbiological Associates, Inc. (Bethesda, MD), for determination of antibody titers. The laboratory serology methods and viral agents for which testing was performed are tabulated blow; the times during the studies at which blood was collected for serological testing are also listed.

Test and Method	Time of Analysis
Rats	
14-Day Studies	
Hemagglutination Inhibition	
PVM (pneumonis virus of mice)	Study termination
Sendai	Study termination
KRV (Kilham rat virus)	Study termination
H-1 (Toolan's H-1 virus)	Study termination
Polyoma virus	Study termination
Complement Fixation	
RCV (rat coronavirus)	Study termination
13-Week Studies	
Hemagglutination Inhibition	
PVM	Study termination
KRV	Study termination
H-1	Study termination
Complement Fixation	
Sendai	Study termination
RCV	Study termination
2-Year Studies	
Hemagglutination Inhibition	
KRV	6, 12, 18, and 24 months
H-1	6, 12, 18, and 24 months
ELISA	
Mycoplasma pulmonis	6, 12, 18, and 24 months
Mycoplasma arthritidis	6, 12, 18, and 24 months
PVM	6, 12, 18, and 24 months
Sendai	6, 12, 18, and 24 months
RCV/SDA (rat coronavirus/sialodacryoadenitis virus)	6, 12, 18, and 24 months
CARB	24 months

Test and Method (continued)	Time of Analysis (continued)
Rats (continued)	
Stop-Exposure Study	
Hemagglutination Inhibition	
KRV	6, 12, 18, and 24 months
H-1	6, 12, 18, and 24 months
ELISA	
Mycoplasma arthritidis	6, 12, 18, and 24 months
Mycoplasma pulmonis	6, 12, 18, and 24 months
PVM	6, 12, 18, and 24 months
Sendai	6, 12, 18, and 24 months
RCV/SDA	6, 12, 18, and 24 months
CARB	24 months
Mice	
14-Day Studies	
Hemagglutination Inhibition	
PVM	Study termination
Reovirus 3	Study termination
GDVII	Study termination
Sendai	Study termination
MVM	Study termination
Ectromelia virus	Study termination
Complement Fixation	
Mouse adenoma virus	Study termination
LCM	Study termination
RCV	Study termination
ELISA	
MHV	Study termination
13-Week Studies	
Hemagglutination Inhibition	
PVM	Study termination
Reovirus 3	Study termination
GDVII	Study termination
MVM	Study termination
Ectromelia virus	Study termination
Complement Fixation	
Sendai	Study termination
Mouse adenoma virus	Study termination
MHV	Study termination
LCM	Study termination

Test and Method (continued)	Time of Analysis (continued)
Mice (continued)	
2-Year Studies	
Hemagglutination Inhibition	
K (papovirus)	6, 12, 18, and 24 months
MVM	6, 12, 18, and 24 months
Complement Fixation	
LCM	6, 12, and 18 months
ELISA	
Mycoplasma pulmonis	6, 12, 18, and 24 months
Mycoplasma arthritidis	6, 12, 18, and 24 months
PVM	6, 12, 18, and 24 months
Sendai	6, 12, 18, and 24 months
MHV	6, 12, 18, and 24 months
Ectromelia virus	6, 12, 18, and 24 months
GDVII	6, 12, 18, and 24 months
Reovirus 3	6, 12, 18, and 24 months
Mouse adenoma virus	6, 12, 18, and 24 months
Immunofluorescence Assay	
EDIM (epizootic diarrhea of infant mice)	6, 12, 18, and 24 months
LCM	24 months

RESULTS

The serology results for sentinel animals are presented in Table M1.

TABLE M1
Murine Virus Antibody Determinations for Rats and Mice
in the 14-Day, 13-Week, 2-Year, and Stop-Exposure Feed Studies of *o*-Nitroanisole

	Interval	Incidence of Antibody in Sentinel Animals	Positive Serologic Reaction for
14-Day Studies			
Rats	14 days	0/10	None positive
Mice	14 days	0/10	None positive
13-Week Studies			
Rats	13 weeks	0/10	None positive
Mice	13 weeks	0/10	None positive
2-Year Studies			
Rats	6 months	1/10	Possible *M. arthritidis*
	12 months	1/10	Possible *M. arthritidis*
	18 months	0/9	None positive
	24 months	0/10	None positive
Mice	6 months	0/10	None positive
	12 months	1/9	Possible *M. arthritidis*
	18 months	1/8	Possible *M. arthritidis*
	24 months	0/10	None positive
Stop-Exposure Study			
	6 months	1/9	Possible *M. arthritidis*
	12 months	1/10	Possible *M. arthritidis*
	18 months	1/10	Possible *M. arthritidis*
	24 months	1/10	Possible *M. arthritidis*
